recovered from medieval and postmedieval cesspits. This prompted a number of hypotheses: (1) *T. zosteræ* was able to live in medieval cesspits, feeding on sewage; (2) seaweed was being imported into medieval towns; (3) *T. zosteræ* had altered its environmental requirements between modern and medieval times; or (4) a closely related, undescribed species of *Thoracochaeta* that feeds on sewage existed in the past and became extinct, or has as yet to be recorded. Taxonomists established that the archaeological and modern flies were indistinguishable from each other and therefore should be considered to be the same species—dismissing one hypothesis. Isotopic analysis of $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ ratios, in both the modern and the archaeological puparia, and their likely larval food, seaweed and sewage respectively, showed that the modern flies had a marine diet, whereas the archaeological flies had a terrestrial diet. This indicated that *T. zosteræ* formally inhabited medieval cesspits, feeding on sewage. It is thought that medieval open cesspits that would have contained both wet and drying decaying matter were ideal for *T. zosteræ*, unlike modern closed cesspits, which remain constantly wet. Thus it is clear that the seaweed fly used to thrive in a habitat for which there is no modern equivalent and that its presence in medieval towns does not provide evidence for the presence of seaweed (Webb, Hedges, and Robinson 1998).

Because of the need to take such complexities into account, researchers, rather than relying on single species, consider assemblages as a whole, recording the range of taxa present and their relative abundance. From this, and with reference to ecological data and ethnographic data, indicator packages (see ARCHAEOENTOMOLOGY), taxocenes (see LAND AND FRESHWATER MOLLUSCS), and transfer function methods have been developed. These consider the communities of different types of biological remains that occur together, and in roughly the same proportions, as indicative of particular environments, and are continually being refined through studies of modern analogues and as more paleoecological data becomes available.

In tandem with these methods, a multi-proxy approach, whereby different lines of environmental evidence are brought together to arrive at more accurate and nuanced interpretations of the paleoenvironmental record,

is generally employed. This allows for differences in the responses of different groups of organisms to be taken into account, including rates of colonization and varying competition. For example, the presence of alder leaf beetle (*Agelastica alni*) in a deposit formed within a paleochannel indicates the previous existence of alder with the catchment. The relative abundance of alder pollen, as compared to the pollen from other trees within the same deposit, could suggest the likely extent of alder growth within the catchment and what other trees were growing in the area. The recovery of macroscopic plant remains of alder, such as seeds, catkins, and buds, could indicate that alder was growing on the banks of the channel, and even in rapidly accumulating deposits; and it could suggest the season when the deposit formed. In addition to this evidence, remains of chironmids, ostracods, mollusks, and diatoms preserved within the same sediments could be used to explore water quality in the former channel and to provide information on depth, flow, substrate, and nutrient status.

Similar approaches and methods can be used to answer paleoeconomic questions. Multidisciplinary studies of dairying have employed a combination of zooarchaeological methods, stable isotope analysis, and organic residue analysis of ceramics to understand the evolution of dairying practice. A combination of different methods can also be employed to understand human behavior, including single events, for example a bustum burial at Biddenham Loop, Bedfordshire, England. Through integration of human osteoarchaeological, zooarchaeological, charcoal, and artifactual evidence from the burial pit, it was possible to establish that the adult male was laid on the pyre in an extended position, with a dog placed at his feet. Charcoal found in association with iron nails in the same feature suggested that the corpse may have been laid on a decorated funeral bed (Baker and Worley 2014, 44).

Future directions

Advances in biomolecular techniques, in particular next-generation sequencing of DNA, the development of stable isotope analysis, and organic residue analysis, have opened up new avenues of environmental research,

allowing us to address questions concerning the evolution of animals and plants, domestic species, biogeography, diet, and environmental change in far more detail than was possible even 10 years ago. At the same time, the application of computational modeling techniques, which allow the testing of different scenarios in paleoenvironmental reconstruction, has revealed considerable potential as well as shown the limitations of our data.

Research by archaeoseismologists and archaeovolcanologists is helping people who live in earthquake zones and in areas with active volcanos to understand the biographies of people from those places and to provide information to hazard managers and disaster planners. Environmental archaeology can also inform responses to climate change, not only in terms of heritage management but also by offering lessons from the past that can be used to inform climate adaptation measures and to suggest how to tackle pollution. This has prompted the suggestion that environmental archaeologists should play a greater role in debates concerning the future of humans on planet Earth and be more upfront about their ethical stance (Riede, Andersen, and Price 2016).

Humans are capable of adapting to a wide range of environments; they are ecosystem engineers par excellence. Understanding the ways in which people have coped with disasters and environmental changes in the past, including embarking on huge cultural changes, shows that the future holds a wealth of possibilities for solving the challenges humans face at the start of twenty-first century.

Environmental Management with Fire

MICHAEL R. COUGHLAN
University of Georgia, USA

The systematic use of fire to manage the environment is one of the most ecologically important behavioral characteristics of humans. Fire consumes vegetation, differentially inhibits plant growth and reproduction, and modifies soil properties. It is a key ecological disturbance and evolutionary force in nearly every terrestrial biome on Earth. Humans are the only animal to master the use of fire and this ability has enabled humans to completely transform landscapes.

As ecosystems engineers, humans habitually modify their environments through daily provisioning. Fire has long been a key component of human provisioning strategies, facilitating efficient manipulation of the distribution, productivity, and diversity of natural resources. The use of fire helped to broaden the reach of human activity to the landscape scale. It was with the ability to set fires that humans first became agents of broad-scale ecological disturbance.

At the site-scale, evidence for hominin fire-making is documented between 1.5 to 0.3 Ma, predating the emergence of anatomically modern humans. As a requisite to sustaining hearth-confined fire, humans learned to “feed” fuel to embers or ignited tinder. Given the cognitive processes involved in learning to master fire in this way, it is difficult to imagine that the confined use of fire significantly predates the casual setting of landscape fires. Armed with the knowledge and skill to ignite fires, humans eventually learned how to selectively broadcast fire across the landscape by taking advantage of weather and topography through the precise timing and placement of ignitions. This step in our relationship with fire allowed for the transformation of fire use from simple environmental disturbance to a powerful tool of environmental management.

Fire use rationale

Historical and contemporaneous human groups have been observed using fire in a myriad of ways and in a variety of environments. Fire is used by hunter-gatherers in both immediate and delayed return foraging contexts. The scale of environmental consequences of the use of fire by hunter-gatherers remains highly debated. Among hunter-gatherer groups who have been documented using fire, immediate return hunting is one of the most commonly cited reasons. For hunting, “game drive” fires are set in order to flush prey from the cover of trees and shrubs. For example, the Paiute of the North American Great Basin historically used fire in sagebrush range to encircle black-tailed jack rabbits (*Lepus californicus*) and drive them toward a group of men, women, and children armed with clubs (Steward 1938). Paiute also used fire to flush larger game such as pronghorn antelope (*Antilocapra americana*) and deer (*Odocoileus* spp.) into the open from forested portions of the mountains. One of the most cited examples of the historical use of fire to manage the environment is the “fire-stick farming” of Australian Aboriginals (Jones 1969). In the western desert of Australia, the Martu people continue to use fire to burn mature spinifex (*Triodia* spp.) savanna for locating small burrowed game such as the monitor lizard (*Varanus indicus*) (Bird, Bliege Bird, and Parker 2005).

Many hunter-gatherers groups also used fire to improve the productivity of commonly foraged pyrophilic and fire-tolerant vegetation such as berries, tubers, and nut-bearing trees. In California, Native American groups used fire along with coppicing to encourage specific morphological traits in fibrous plants harvested for basketry, cordage, and other purposes (Anderson 1999).

Probably the most common use of fire today is for preparing agricultural fields before planting or after harvesting. Fire prepares soils for planting by clearing unwanted biomass and converting it into charcoal (carbon) and potash (potassium) which serve as nutrient amendments that

help increase an agricultural plot's productivity. Agricultural uses of fire date to the very beginning of the Neolithic and are likely to be associated with domestication at the species level and coevolutionary processes at the agro-ecosystem level. Agriculture fire use is extremely diverse ranging from annual stubble burning to fire-fallow cultivation. The latter group of practices goes by many names, for example slash-and-burn, swidden, shifting cultivation (Conklin 1961). Fire-fallow generally involves cutting and burning brush and trees from a plot just prior to planting cultigens. Although new plots can be cleared from old growth forests, fire-fallow most often involves the clearance of secondary forest or seral vegetation.

Pastoral fire is another widespread practice. Pastoralists burn grasses and shrubs in order to encourage the growth of more palatable vegetation. Importantly, combusted biomass provides carbon and potassium as soil amendments, often improving pasture productivity. Pastoral fire regimes involve frequent, low-severity fires that help grasses to outcompete shrubs. Many heathlands, subalpine pastures, and savannah landscapes are maintained by the frequent application of fire.

Socioecological dynamics

Weather, topography, and fuel characteristics control variability in fire spread and intensity which, in turn, determine the severity of fire effects on the environment (Agee 1993). Some landscapes maintained by human fire use involve extensive, low-severity fires that inflict minimal disturbance on ecological conditions. In the subalpine altitudinal zone of the western Pyrenees (800–1600 msl), Basque pastoralists set fires in the late winter and early spring. Today, pastoral fires prevent processes of ecological succession and mitigate selective forces of grazing and browsing, thus maintaining a relatively stable forest-pasture landscape mosaic. Over the long term such fires converted large areas of forest to pasture and significantly altered the properties of soils in ways that facilitate their use and conservation. The emergent human-fire-landscape dynamic is self-organizing in that it requires

little if any active fire management or suppression beyond consideration of the timing and placement of ignitions by individual farmers. Fires follow pathways through the landscape predetermined by vegetation, specific weather conditions, and topographic microclimates. The landscape patterns that emerge from pastoral fire use help to structure land tenure at the community-level and constrain the nature and potential of household-level land holdings (Coughlan 2014).

In other landscapes, smaller, moderate to high severity fires maintain a fine-grained patchwork of early and late successional vegetation, through a rotational firing of land. In these landscapes fire achieves a metastability of pattern and process over the long term. For example, the use of hunting fires by the Martu of Western Australia scales landscape mosaic in ways that increase heterogeneity, biological diversity, and buffer climate-driven disturbances. Martu fires are smaller than the natural regime of lightning-caused fire, in part, because the Martu light fires under more moderate fire weather conditions. Over time, patterns of residential mobility and hunting-fire practices interact to form an emergent mosaic of fuel conditions that helps self-limit human- and lightning-ignited fires. The resulting pyrodiversity helps structure inter- and intragroup socioeconomic relationships for managing productive landscapes across generations (Bird et al. 2016).

Archaeological investigations, multi-proxy and multiscale

Archaeologists routinely study the traces of manipulations of the environment that evidence subsistence strategies, social organization, and beliefs. The archaeological investigation of fire management began in the 1920s with Grahame Clark's multidisciplinary approach to Neolithic settlement in Europe (Clark 1947). Clark incorporated settlement archaeology with studies in palynology (see PALYNOLOGY), sedimentary charcoal (see CHARCOAL AND WOOD ANALYSIS), and ethnoarchaeology (see ETHNOARCHAEOLOGY) to posit Neolithic forest clearance by fire-fallow cultivation.

Yet, in spite of nearly 100 years of study, archaeologists have spent relatively little time investigating management using fire. This deficiency may relate to the fact that archaeological investigation tends to take place at the site-level. Although site-level data such as paleoethnobotanical remains (see also PALEOETHNOBOTANY) provide an important form of evidence for understanding the ancient use of management fire, the study of off-site fire use inherently requires a landscape perspective.

More robust studies of fire use take a multiproxy approach and often include methods from paleoecology such as palynology, magnetic susceptibility (see MAGNETIC SUSCEPTIBILITY), phytolith analysis (see PHYTOLITH ANALYSIS), and stable isotopes in paleoethnobotany (see PALEOETHNOBOTANY AND STABLE ISOTOPES). One key development in the last few decades involves the analysis of sedimentary charcoal (microcharcoal). Clark and Royall's (1995) study of charcoal sediments from Crawford Lake in Ontario, Canada was foundational in this area. Clark and Royall show that changes in forest composition are associated with ancient occupation of the area by Iroquois peoples. Importantly the authors link archaeological evidence for Iroquois land use with evidence for increased fire activity. Research efforts that combine studies of sedimentary charcoal with archaeological investigations are now underway in a number of areas.

A major limitation to the use of sedimentary charcoal has been the fact that the high-altitude lacustrine environments that provide reliable sedimentary archives are normally on the peripheries of human land use. As a consequence, investigators have sought out archaeological sites in proximity to lower resolution sedimentary archives found in bogs, mires, and colluvium. Mismatches between paleoecological and archaeological scales of investigation present challenges for combining these data, however modeling efforts may yet resolve such analytical difficulties.

Dendrochronological evidence for fire is another area in which proxies for changes in fire frequency can be linked with archaeological or ethnohistorical evidence of occupation. Recent studies evidence past fire use and management in North American ecosystems as diverse as

the temperate rainforests of the Pacific Northwest, California central coastal Redwood forests, Eastern Oak-hickory woodlands and the montane Ponderosa Pine forests of New Mexico. Dendrochronological research is of interest to archaeologists because its resolution is subannual and it can often provide information on both climate as well as local environmental conditions.

Due to the relevance of ancient management fires to paleoecological reconstruction, many studies involving past human-caused fires have proceeded without the aid of archaeologists. As a consequence of this legacy, the relationship of fire use to the archaeological record remains largely obscured. As reviewed above, archaeologists have begun to address this gap. In part, this has been accomplished through participation in collaborative, interdisciplinary environmental science projects. Moving forward, archaeological science must continue to refine methodological approaches to understanding how peoples in the past used fire to manage their environments.

Environmental Management with Livestock

KARI LOE HJELLE and MONS KVAMME
University of Bergen, Norway

Since their domestication, livestock have been important in shaping vegetation and landscape. Animal husbandry was introduced into the mostly forested landscapes of northern Europe around 6,000 years ago. Knowledge of the influence of livestock (see CATTLE and SHEEP AND GOATS) on the environment through time has especially been gained through palynology (see PALYNOLOGY), but also analysis of other environmental proxies such as insects (see ARCHAEOENTOMOLOGY) and macroscopic plant remains from lake deposits (see LAKE DEPOSITS) and peat deposits (see PEAT DEPOSITS). Palynological studies show that gradually—and following technological development and societal changes—the landscape was opened up, and managed woodlands, pastures, heathlands, hay meadows, and cultivated fields developed (Behre 1988; Krzywinski, O'Connell, and Küster 2009).

Large areas of the earth's surface are not suited to cultivation; for example, in Norway only three percent of the land surface consists of good-quality arable land, resulting in reliance upon livestock and extensive grazing and fodder collection in semi-natural habitats as part of pre-industrial food production. At the same time, the success of cereal cultivation (see WHEAT and BARLEY, RYE, AND OATS) in the past depended on the presence of livestock that produced dung for manure. Thus, a system of optimal environmental management developed in different geographical areas depending on the available natural resources. These semi-natural habitats, or outfields, are often rich in species and are today in danger of disappearing. With Norway as an example, we present four types of semi-natural habitats—mountain pastures and grasslands,

hay meadows, managed woodlands, and coastal heathlands—that were of vital importance to the traditional farming economy found in many places in the world with comparable landscapes, and in remote areas even today.

Mountain pastures and grasslands

In Norway, seasonal grazing of mountainous areas was traditionally organized as “summer farming.” It kept the livestock away from areas close to the settlements where the main production of crops and winter fodder took place, and made use of the resources of remote parts of the farm. Mountain grass productivity can be very high, and the best way to exploit this resource is to keep the livestock in these grasslands during the summer. The cattle had their calves in spring, and thus milk production was at its highest when the animals had access to the best fodder. To look after the cattle, people stayed in small cabins at the summer farms during the grazing season. The products (mostly cheese and butter) were transported regularly down to the main farm. Many farms had several temporary stations where they kept the cattle for some weeks during late spring/early summer until conditions became favorable at higher altitudes. Some of these areas were used for haymaking late in the summer before the cattle were taken down for the winter.

Archaeological and botanical evidence indicates that grazing in mountainous areas was already taking place 4,000 years ago in some places. It is, however, not until the fourth century CE and later that house remains are found at summer farms. Paleoecological studies indicate that the development of the historical grazing landscape at the summer farms started at about the same time. Probably these findings are related to the settlement history in corresponding areas at lower altitudes. Iron Age mountainous land-use probably differed from later specialized dairy farming (see DAIRYING), but the impact on the vegetation and the landscapes was very much the same.

Hay meadows

In temperate areas, hay has been an important winter fodder for millennia. As most of the arable land was needed for crop production, much of the hay had to be procured elsewhere. This was mainly done by cutting “hay” from flood meadows, naturally fertilized by flood water from rivers, or from semi-natural grasslands. These grasslands were never plowed or fertilized, although surface stones were removed to facilitate mowing. Natural fertilization occurred through grazing in early spring or autumn, to allow the hay crop to grow until July when haymaking normally started, but the most remotely situated meadows were not harvested until late in the summer. Many places had small barns within the meadows to store the hay temporarily. Fens were also mown, but they were only harvested every second or third year. As a result of these management regimes, in particular the exclusion of livestock at certain times of year and the taking of hay crops, these grasslands developed into semi-natural habitats of high biodiversity. Even today some of them rank among the most species-rich biotopes in Europe (Wilson et al. 2012).

Multivariate data analysis, modern analogs (surface pollen samples), and high-resolution pollen identification indicate that, in Norway, hay meadows originated during the Iron Age (500 BCE–1030 CE). This corresponds with the development of the iron scythe, a tool that facilitates mowing on a large scale.

Managed woodland

Dried leaves and twigs from broad-leaved trees were also used for winter fodder, especially elm, ash, and birch. Leafy twigs were cut in late summer when the leaves were still full of nutrients and knitted up in small bundles. The bundles were hung to dry in appropriate places and later transported to a barn or stored outside in special stacks. The most common method to harvest the trees was to make pollards; young trees were cut at appropriate height and the re-growth harvested about every fifth year (see CHARCOAL AND WOOD ANALYSIS).

For the harvest of leaf fodder, a special knife was developed in the Iron Age. However, in contrast to haymaking, which requires an iron scythe to be done efficiently, leafy twigs can easily be harvested using stone tools. Leaf harvesting is probably one of the oldest techniques of fodder collection for livestock. The antiquity and origin of the leaf fodder collecting is a classical question in palynology—for example, the cause of the elm decline detected all over northern Europe around 6,000 years ago which is now regarded to be a combination of elm disease and human impact. However, several local pollen diagrams from Norway show beyond any doubt the harvest of elm leaves from the Late Neolithic onwards. Probably other broadleaved trees were also harvested, but this is difficult to detect in the pollen diagrams as these trees produce flowers between each harvest, in contrast to elms that take longer to resume flowering following harvest. Although work is in progress, it is still a challenge to identify these woodlands in the pollen record (Bunting, Grant, and Waller 2016).

Coastal heathlands

Open coastal heathlands dominated by dwarf shrubs, mainly heather (*Calluna vulgaris*), developed from the special way coastal farming was adapted to the oceanic climate. Due to the Gulf Stream, the winters on the coast are much milder than elsewhere in Norway, with little or no snow cover. The farmers therefore let the small-stock live outdoors all year round. They survived the winters by eating heather and seaweed. In summertime they would also find grasses and forbs. Young heather is an evergreen plant; the nutrient content of the leaves is more or less the same during winter and summer. With access to sufficient areas of heathland in good condition, the animals had no problems surviving normal winters without any extra fodder. In order to maintain the fodder quality of the heather plants, the heathlands were regularly set on fire to rejuvenate the heather. This burning was always done during the winter in order to avoid damage to the roots and the seed bank in the soil. Each year, patches of heathland were burnt while others were left,

creating a mosaic of heather at different developmental stages, in addition to grasses and forbs.

From detailed studies, combining archaeology and palynology, it has been shown that there is a close connection between farming settlement, deforestation in surrounding landscapes, heathland development, and heather burning. The timing of heathland formation can vary both locally and among regions depending on farming conditions; several thousand years can separate the age of heathlands on two neighboring islands and also between regions: At Jæren, an area of early farming in southwest Norway, heathland formation started during the Neolithic, with most of the heathlands forming during the Bronze Age. In marginal farming areas along the coast north of Bergen, the Iron Age and early Medieval Age were more important periods. Both detailed and regional studies thus demonstrate that coastal heathlands in Norway have an anthropogenic origin.

Future directions

Although palynology is the main method used to gain information about vegetation development through time, interdisciplinary research is becoming increasingly important; close collaboration with archaeologists is needed to understand environmental management by livestock in earlier time periods, knowledge of the effects of different management regimes (e.g., type and number of grazing animals) on the vegetation is gained from ecological research, paleoethnobotany (see PALEOETHNOBOTANY) (plant macroremains from archaeological contexts) can elucidate the types of plants collected for fodder (see ENVIRONMENTAL ARCHAEOLOGY), and historical records bridge the gap between recent time and prehistory (Behre 1988; Birks et al. 1988; Krzywinski et al. 2009; Hjelle et al. 2012).

Palynological methods are also developing and several of these advances are important for research into environmental management with livestock. Modern analogs, that is, pollen surface samples from managed vegetation types (Krzywinski et al. 2009, 40, 201), have been shown to be useful in reconstructing past

land-use practices, and increased knowledge of the ecology of non-pollen palynomorphs (Schlütz and Shumilovskikh 2017) may make this proxy more widely used in the future. High-quality microscopes make higher pollen taxonomic resolution possible and may aid the determination of indicator taxa for different management regimes. Knowledge of pollen productivity in managed landscapes (Bunting et al. 2016) has become increasingly crucial as quantitative reconstruction methods have developed. A greater understanding of the size of the area reflected in a pollen sample is being developed (Sugita 2007); pollen diagrams from large and small sites reflect the vegetation differently and analysis of a number of sites can aid identification of the spatial extent of a habitat through time. On-going research in developing and improving quantitative reconstructions of past vegetation and landscapes (Gaillard et al. 2008; Sugita 2007; Bunting et al. 2016) has the potential to contribute to the understanding of the importance of environmental management with livestock in past societies.

Erosion

GIANNA AYALA

University of Sheffield, UK

The study of erosion has been a key topic in a wide range of archaeological research projects across the world for the last 50 years. Erosion is of global importance when discussing sustainable land use (past and present), human impact upon the landscape, landscape change, and the effect that erosion processes have had on the formation and preservation of the archaeological record. Erosion is the breaking down, movement, and deposition of soil and rock by the action of water, wind, or ice, which can be accelerated by seismic activity, climate change, and human action. In the process of erosion, the broken down material is moved from the place of weathering by a flowing agent such as water (hillwash or alluvial activity), ice in the form of glaciers, or by the wind. Mass movement, also known as mass wasting, is the movement of material down slope due to gravity in creeps, landslides, rock falls, and debris flows.

While studies focusing on erosion as a result of human impact have been undertaken across the globe, the Mediterranean landscape is a particularly useful case study because of its natural vulnerability to erosion resulting from a combination of its geological make-up, frequent tectonic activity (see *ARCHAEOSEISMOLOGY*), along with a semiarid climate that has seasonal variations in the amount and intensity of rainfall and the vegetation that this supports. These factors, coupled with a long and continuous occupational history, allows for the high-resolution study of the interaction of driving forces and rates and timings of periods of increased erosion.

Many of these Mediterranean studies have centered on the way in which hillslope processes have influenced the amount of sediment transported by water and gravity down slope and into river systems (see *RIVER SYSTEMS*). While on the one hand the movement of the soil is driven by climate, specifically seasonal distribution, quantity, and intensity of the rainfall, another

determining factor is the type of vegetation cover (dependent on the geology and soils that can support it). Vegetation can protect the soil and anchor it onto the slopes. Human modification of vegetation cover through clearance and land use (tillage and grazing) has been seen to have a direct effect on the amount of material eroded, that in turn increases the sediment load within alluvial systems. However there has been considerable debate about the relative importance of human influence on erosion rates.

One of the most significant pieces of research on Mediterranean erosion is Vita-Finzi's (1969) seminal publication, in which he identified two major phases of valley aggradation which he attributed to the last glacial period (Older Fill) (c.30,000–10,000 BP) and to Late Roman and medieval periods (Younger Fill) (AD 400–1850). Vita Finzi identified these two phases of alluviation in valleys across the Mediterranean and argued that they were the result of climatically driven erosion.

Vita Finzi's research has had a considerable influence on Mediterranean landscape studies, especially in landscape and regional archaeology as it served as the first long-term, large-scale developmental model which subsequent researchers have been able to compare to their own findings. It has also been at the root of an ongoing debate concerning the identification of triggers of increased erosion; that is, whether periods of increased erosion are climatically or anthropologically driven.

Mediterranean erosion studies have also been influenced in the 1990s by large European Union-funded projects which aimed to address modern concerns about increasing landscape degradation and desertification. MEDALUS (Mediterranean Desertification and Land Use), and the Archaeomedes project, incorporated an historical and at times archaeological component. MEDALUS set out to investigate and model the specific physical processes of desertification in the Mediterranean; viewing this as a result of long-term erosion derived from the interaction of extreme climatic events and intensification of land

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0220

use in the historic period which tipped vulnerable landscapes past regenerative thresholds. The Archaeomedes project (1992–94) also sought to understand the process of landscape degradation and desertification, though from a more cultural perspective, and over a longer time period.

These projects made a direct link between land use and increased erosion in contemporary landscapes and were focused on defining the crucial thresholds beyond which the landscape could not regenerate (recover) and desertification took hold. This idea of “degradation” in the sense of loss of fertility and inability to regenerate entered academic language (see Butzer 2005 for a review) although critics of these projects, most notably Grove and Rackham (2001) took issue with the use of terms like “degradation” as unduly negative and have suggested that the role of the “human” element in erosion has been overstated.

A number of important geoarchaeological studies of landscape evolution that have taken place since the 1990s have stressed the dominant role of human management or mismanagement of land use practice which can be seen in the sedimentary record. The study of these landscapes has also been greatly enhanced by advances in fine resolution palaeoclimatic reconstructions based on several lines of environmental evidence (see PALEOENVIRONMENTAL RECONSTRUCTION). This palaeoclimatic evidence in conjunction with intensive small-scale valley studies has necessitated a reevaluation of the role of climate as increasing the vulnerability of a landscape to the effects of human disturbance (Bintliff 2000 and Butzer 2005 and references therein). Bintliff (2000) takes this further, stressing the impact of extreme climatic events on these already fragile landscapes.

Human modification of the landscape in the form of agricultural terracing is seen as an attempt to increase arable land by stabilizing steeper hillslopes, conserving pockets of arable soil and retaining as much rainwater as possible. Terraced landscapes reflect long-term investment of resources and energy, including preparation (leveling and clearance), cutting into the hillside and transportation of soil, as well as the building and maintenance of the terrace walls.

Studies of agricultural terraces have not only identified their antiquity (beginning in the Bronze Age (c. 3200–1500 BC) in many locales in Spain,

Italy, and Greece) and methods of construction, but also their role in landscape history. The dating and characterization of sequences of palaeosols and colluvial deposits that have accumulated after their construction provide insights into past land use as well as direct evidence of soil movement, offering high resolution data to establish the timing of erosion events (French and Whitelaw 1999; Krahtopoulou and Frederick 2008). The construction and maintenance of terraces can be seen as soil redistribution throughout the landscape in the short term instead of directly inhibiting soil loss over the long term (Bevan and Conolly 2011).

Terracing has often been cited as having an effect on valley fills. When they become abandoned or not maintained, their reservoir of captured soil is released down slope. Research on the island of Kythera has shown that after terrace abandonment, the main types of erosion are sheet wash (the removal of fine soil material overland by rainwater) and gully erosion (when slopes are sharply eroded by water that carries away exposed soil material) which on unconsolidated geology can greatly increase erosion of the slope and increase sediment flux within the local fluvial system (Krahtopoulou and Frederick 2008: 559–60). Recent work on historic agricultural terraces supports the findings of increased erosion after abandonment. It is clear, however, that terraces, just like the fills of alluvial systems, are complex and highly variable across the Mediterranean. The rate and extent of terrace degradation and subsequent erosion of the hill slope after their abandonment reflect the interactions of specific localized environmental factors (including geology and soil properties, topography and slope, the location of the terraces on the slope, and climate) and land use practices, terrace design, and maintenance.

Intensive archaeological survey in the Mediterranean has revealed an artifact-rich landscape, but the processes that created the abundance of archaeological evidence on the surface, particularly that from certain periods of history, are not fully understood. A recurrent theme in archaeological regional surveys has been to assess the “visibility” of the archaeological record on the surface, not only in terms of ground cover but also in terms of soil stability. Studies have attempted to compensate for differential visibility of material in terms of factoring in differences in

vegetation and geomorphology or have involved small-scale investigations on tillage and site disturbance. Erosion has been identified as a significant dynamic in the creation of the archaeological record, particularly in regions of the Mediterranean that are dominated by highlands and mountain ranges.

It should now be best practice for archaeological field surveys to include geoarchaeological analysis that assesses, among other things, the formation processes (see FORMATION PROCESSES) that have affected the presence of archaeological material on the surface. Central to this assessment is the examination of slope stability and an evaluation of the likelihood that material has either been disturbed or buried by past or more recent erosive processes. These investigations treat archaeological contexts, once they are enveloped within the soil matrix, as sediments, subject to the same physical processes. There are an increasing number of research projects that have undertaken regional erosion studies to enhance our understanding of the visibility and preservation of archaeological material (Ayala and Fitzjohn 2007). These investigations highlight the necessity of examining field-survey data in relation to the geomorphological development of a region, prior to interpreting the record as evidence of settlement patterns and regional history.

Geomorphological processes are considered a key factor in the preservation and visibility of archaeological surface finds across the landscape. With the adoption of geographical information systems GIS, the ability to model the erosive potential or risk that a landscape has been exposed to allows for the analysis of the complex relationship between ancient human strategies, geomorphic processes, and surface exposure of archaeological finds (Ayala and Fitzjohn 2007). Current developments of erosion models using GIS and other agent-based modeling software are not only used to reconstruct landscape evolution and predict rates of erosion but also, with the incorporation of historic and archaeological data, the land use choices and decision-making processes of past societies. While there is a tradition of geomorphological research into decision making and land use and land-cover change (LUCC) and the effects it has in erosion and patterns of landscape evolution (Wainwright and Millington 2010 and references therein) within

Mediterranean landscapes, it has only recently become part of the archaeological dialogue.

One of the most exciting potentials of this type of computational modeling is its ability to test different simulations of past land use choices as seen in the record of long-term environmental change. This active and dynamic way of testing different land use scenarios has been used in conjunction with surface survey results to analyze potential settlement and land use choices as well as isolating single management methods (i.e., terracing) and predict their original coverage and impact upon the landscape (Bevan and Conolly 2011). Exciting applications of agent-based models have also been created in an attempt to improve our understanding, or to support analysis of past societal interactions with the landscape and their potential impact on those landscapes.

Fish

REBECCA NICHOLSON

Oxford Archaeology, UK

Fish have been consumed by people from the earliest times, as evidenced by both fish bones and fishing artifacts found at sites of human occupation. Shell fishhooks from Sakitari cave in Japan and the Jerimalai site in East Timor show that line fishing was practiced over 20,000 years ago, and at the latter site, tuna bones evidence fishing offshore as early as 42,000 BCE. At Blombos cave in South Africa, fish bones suggestive of inshore fishing have been identified in contexts dating from the Middle Paleolithic at 140,000–50,000 BCE, while in Europe evidence for fishing has been recovered from a number of Upper Paleolithic cave sites.

Although there are currently over 33,000 fish species, bones regularly recovered from archaeological contexts are usually from a fairly restricted range of taxa, with species exploited reflecting the available habitats (freshwater, estuarine, coastal, oceanic), resources, and technologies, fish behaviors (solitary, shoaling, pelagic, etc.), palatability, societal beliefs, and the economic strategies practiced by fishing communities.

Prior to industrialization and the development of deepsea fisheries (see DEEP-SEA FISHERIES), across the world most fish were captured in fairly shallow water using a variety of different nets and traps—often associated with fences or weirs, spears, harpoons, and leisters, gorges, hooks, and lines operated from the shoreline or from boats in coastal waters. There is a substantial literature documenting fishing prosecuted by coastal communities both historically and in the present day; Fenton (1997), for example, describes the many types of fishing practiced by the inhabitants of Orkney and Shetland over many centuries. Here, small inshore fish, predominantly saithe (*Pollachius virens*), provided not only protein but also oil, extracted by boiling the livers, which was

used as a crude lamp oil possibly from ancient times (Nicholson 2004).

Cut marks can indicate butchery methods, but it is possible to portion a fish without leaving discernible marks on the bones. The presence or absence of certain skeletal elements can also provide evidence for the preparation of fish for the table or techniques of fish preservation.

Fish that are seasonally abundant, such as salmon which migrate from the ocean to the upper reaches of rivers to spawn, have been fished throughout human history. Investigations into Pacific salmon fisheries by Campbell and Butler (2010) have shown the resilience of this fish to human exploitation over the last 7,500 years despite changes to both the ecological and social systems. European eels (*Anguilla anguilla*), which famously migrate from freshwater and estuaries to spawning grounds in the Sargasso Sea, have been the focus of major fisheries during both their migration downstream as silver eels and their migration upstream as elvers. During the medieval period in England they were so important that the Domesday Book and other medieval documents frequently record rents paid in eels, and weirs choked many rivers.

Apart from offshore, coastal, and riverine fishing, fish have been cultivated in ponds across the world and since at least the Roman period in Europe. Fish ponds were a common feature of royal and monastic estates in medieval times, when fish consumption accelerated as a response to urbanization and ecclesiastical edicts, since fish could be eaten on days when four-legged beasts could not. Some fish, including sturgeon and pike (*Esox lucius*), have been protected by royal ordinances and their remains, together with those of other large and expensive fish, can be considered markers of social status.

Fish remains can also provide evidence for trade, one obvious example of which is the trade in salted and fermented fish products around the Roman empire and beyond. Usually produced from fish blood and intestines or small oily fish such as sardines (*Sardina pilchardus*) and mackerel (Scombridae), fish sauces including

muria, *altec*, *liquamen*, and *garum* were popular condiments in the classical world. Evidence for the movement of these products, together with salted fish (*salsamenta*), is provided by distinctive collections of fish bones as well as written records and the amphorae used to store and transport them. Other techniques that have proven potential in this area include the analysis of aDNA (see ZOOARCHAEOLOGY AND ANCIENT DNA) and lipids (see ORGANIC RESIDUE ANALYSIS).

The interpretation of fish remains in paleoecological and paleoeconomic reconstruction is influenced by the ways in which the archaeological assemblage was created and recovered, as well as any taphonomic biases that may have modified it. While archaeological evidence for fish and fishing activities is largely through the identification of the remains of the fish themselves (bones, scales, otoliths) and inorganic fishing equipment (hooks, weights, weirs), both pre-depositional and post-depositional considerations affect their preservation (for examples see Wheeler and Jones 2009).

Fish bones vary in physical and chemical composition, with some, such as those of the cod family (Gadidae), being relatively large and robust for the size of fish, while cranial bones of salmon and trout (Salmonidae) are thin and fragile, particularly after spawning. Chondrichthyes (sharks, rays, and chimaeras) and Agnatha (hagfishes and lampreys) have skeletons made of cartilage. Only the teeth, dermal denticles (tooth-like structures in the skin), and calcified vertebral centra from sharks and rays are usually recovered archaeologically. The keratinous teeth of lampreys (Petromyzontiformes), attached to a sucker-like mouth in life, are a very rare find, although historically lampreys were a popular food.

Otoliths, distinctive calcium carbonate structures found in the inner ear, survive in alkaline environments, particularly shell middens. They vary in size between different fish taxa and some are much more readily identifiable than others. Scales vary in composition, structure, and size between different types of fish: some form bony plates (ganoid scales) such as the distinctive armour-plating of sturgeon (Acipenseridae), while cartilaginous fish have placoid scales (dermal denticles) and teleosts, or bony fish have leptooid scales which are either ctenoid (toothed

outer edge) or cycloid (circular). While dermal denticles and ganoid scales are fairly robust, ctenoid and ganoid scales are usually only found in waterlogged deposits or where mineralization has occurred, such as in cesspit fills.

Not all fish bones found on an archaeological site necessarily relate to human activity. Other mammals and birds also catch fish or scavenge their remains, and some animals, such as bears and otters, may be responsible for accumulations of fish bones in secluded places such as caves and chambered cairns. Natural fish mortalities also occur, such as the mass die-offs of Pacific salmon (*Oncorhynchus* spp.) after migration and spawning in fresh water.

Prior to the last decades of the twentieth century, most fish bones retrieved from archaeological excavations were recovered by hand. The assemblages so recovered usually almost entirely comprised bones from large fish and, consequently, earlier reports often present a very partial picture of the role of fish and fishing to communities and societies. Today, most excavations employ fine-mesh soil sieving as routine and thus a much wider range of fish bones are recovered, particularly of smaller individuals and species that were often the main target of coastal fisheries.

Identification of fish remains requires access to a comprehensive comparative collection. Although digital identification resources are becoming more common and there are a number of useful identification guides in print, these are best used to gain an overview of diversity and a guide to specific families or genera. Not all skeletal elements are equally diagnostic, and different approaches to identification have been advocated to suit the size of assemblages, diversity of fish found in various geographical locations, and the questions being asked (see discussion and references in Wheeler and Jones 2009, 149–153). The most easily identifiable bones are typically the jaw elements, but some fish have other diagnostic bones, such as the pharyngeal bones of cyprinids (Cyprinidae) and wrasses (Labridae), dermal scutes of sturgeons, and spines of stingray (*Dasyatis* sp.) and catfish (*Synodontis* sp./*Clarias* sp.).

Unlike other animals, fish grow throughout their life and so bone size may not be a useful indicator of species, although bone measurements

can be used to determine fish size if sufficient comparative material is available. Proxy measures used by fisheries researchers include size/age relationships and these can be reconstructed from measurements taken on modern and archaeological bones and otoliths, using allometric regression for species where the modern data have been collected. Incremental growth rings on scales, otoliths, and some bones can be studied to establish fish age and seasonality of capture, but considerable skill is required to accurately interpret the patterns and only extremely well-preserved material is suitable. Seasonality can also sometimes be inferred from knowledge of fish movements and ecology, particularly for migratory species.

Archaeological fish remains have much to offer fisheries science and conservation, providing time depth to investigations of population structures and movements beyond what can be gleaned from written historical records. Evidence of past fish distributions can contribute to a greater understanding of ecological change and aid fisheries management. Excavations at Coppergate, York (UK), revealed a change between the Roman period and the ninth century CE in the kinds of freshwater and anadromous fish recovered, from those found in clean, well-oxygenated water to taxa tolerant of mildly polluted water (Wheeler and Jones 2009, 136). Archaeological evidence for the historical distribution of burbot (*Lota lota*), now extinct in British rivers, can contribute to attempts to re-introduce this freshwater codfish, and archaeological evidence has been used to investigate spatial and temporal changes in the distribution of European eels (Kettle et al. 2008) and sturgeons (*Acipenser oxyrinchus* and *A. sturio*) in western Europe. Analysis of carbon and nitrogen stable isotopes extracted from archaeological fish bone collagen has proved to have considerable potential for identifying fish movements and zones of exploitation in marine and freshwater environments (Orton et al. 2011; Robson et al. 2016). Changes in oxygen isotope ratios within otoliths can be used to investigate changes in water quality and temperature, and, by extrapolation, season of capture.

The contribution of fish and other marine foods to the diet can be postulated both from a study of fish bone assemblages and from analysis of the stable isotopes of carbon, nitrogen, and

sulfur extracted from human bone collagen (see DIET AND CARBON ISOTOPES and DIET AND SULFUR ISOTOPES). A marked decrease in consumption of marine resources, including fish, in the early Neolithic across parts of northwestern Europe has been argued based on stable isotope data from human collagen, although the presence of coastal shell middens containing abundant fish bones particularly in Denmark indicates the likelihood of regional variation (Richards and Schulting 2006). High values of nitrogen and sulfur isotopes have been linked to the consumption of freshwater fish (Nehlich et al. 2011).

With the adoption of these biomolecular techniques, fish and fishing as topics of archaeological enquiry have undergone something of a renaissance, including closer engagement with fisheries science and conservation. While proteomics (ZooMS) and aDNA analyses offer great potential for species identification, they are unlikely to replace more traditional methods, due to cost and availability of equipment. However, these new avenues of research offer exciting opportunities for archaeoichthyologists to engage not only with the past but also with the future.

Flooding

HANNAH FLUCK

Historic England, UK

Flooding occurs when areas of ordinarily dry land are inundated by water from the sea, from inland water bodies such as rivers (see RIVER SYSTEMS) and lakes (see LAKE DEPOSITS), or as a result of surface water run-off. Flooding has influenced (and continues to do so) patterns of human occupation and activity (see INHABITED LANDSCAPES), as well as the formation and preservation of archaeological sites (see FORMATION PROCESSES AND TAPHONOMY). Contemporary flooding impacts the conservation of archaeological deposits and sites, historic buildings and structures, posing challenges for their ongoing preservation. Actions taken to adapt to contemporary and future flood risks, such as construction of flood defenses, can have an impact upon archaeological deposits and affect historic structures, but also present an opportunity to investigate archaeological sites and historic places and learn from past adaptations to flooding.

Identifying evidence of flooding in the archaeological record requires frameworks that incorporate geoarchaeological (see GEOARCHAEOLOGY) and geomorphological (see GEOMORPHOLOGICAL SURVEY) methods to characterize the deposits. Floodplain muds are typical of fluvial flooding in temperate climates, these resulting from finer-grained sediment associated with slower moving or slack flood waters and settling over a wide area. Seasonal or episodic flooding may be indicated by soil development as flood waters dry out. In contrast, deposits associated with flooding from glacial outwash or more high-energy water inundation will be poorly sorted and may include much larger irregular clasts. Paleoenvironmental approaches (see PALEOENVIRONMENTAL RECONSTRUCTION) can help to reconstruct the environmental context for floods, including seasonality and frequency, but the taphonomy of the paleoenvironmental remains themselves can be affected

by the flood processes—for example, in admixing remains from wider contexts. This reworking of material by flood waters and other fluvial processes poses a particular challenge for Pleistocene archaeologists where artifacts and faunal remains frequently occur in disturbed or reworked contexts. Identifying marine inundation, whether as a consequence of transgression (sea-level rise; see SEA-LEVEL CHANGE) or storm surge, tidal surge, or tsunami, is undertaken in a similar way and presents similar challenges. Fauna, including molluscs (see MARINE MOLLUSCS and LAND AND FRESHWATER MOLLUSCS), foraminifera (see FORAMINIFERA), ostracods (see OSTRACODS AND CLADOCERANS), and diatoms (see DIATOMS) can be used to help distinguish between deposits derived from marine or freshwater ingress.

In many instances, investigation of the wider landscape and seascape context will be needed to fully understand the nature, extent, and impact of any flooding event. Geophysical survey may help to map even deeply stratified or submerged deposits, and coring (see CORING), micromorphology (see MICROMORPHOLOGY), and hydrological modeling (see HYDROLOGICAL MODELING) can all contribute. Where significant accumulation of flood deposits has occurred in the past this may obscure earlier archaeology, not just to the passing observer but also sometimes from archaeological prospecting techniques such as field walking, traditional geophysics (e.g., see MAGNETOMETRY and REMOTE SENSING), aerial survey (see AERIAL PHOTOGRAPHY), and light detection and ranging (LiDAR) (see LIDAR DATA VISUALIZATION AND PROCESSING). Investigation of currently flooded landscapes such as those beneath contemporary seas and lakes will require specialist investigation and excavation approaches (e.g., see MARINE EXCAVATION). One such area is Doggerland; today it is an area of seabed in the North Sea, between Britain, Denmark, Germany, and the Netherlands, but 12,000 years ago it was dry land connecting Britain to mainland Europe. Five-thousand years later it had completely vanished beneath the North Sea, a consequence of a series of inundations associated

with sea-level rise. Multidisciplinary research has begun to reveal this lost landscape and its associated archaeology (e.g., Coles 1998; Gaffney et al. 2017).

Seasonal flooding was often welcomed by past societies who made use of the predictable irrigation and rich sediment associated with flood waters. In areas with a monsoon climate (where a seasonal change in winds brings a sudden change in precipitation), such as east and Southeast Asia, the seasonal flooding can be particularly dramatic. It has been proposed that a shift in the monsoon that decreased precipitation contributed to the de-urbanization of the Indus Valley around 4,000 years ago, and similar suggestions have been made for the demise of Neolithic culture in central China around 4,500 years ago (e.g., Wenxiang and Liu 2004). Seasonal flooding of the Nile (in summer) was so important to the people living along its banks because of the rich sediment that the flood waters brought that “nilometers” (Figure 1, right) were constructed in Pharaonic Egypt to measure the depth of flood waters and determine taxation levels according to the harvests that might be predicted (a high flood would mean better crops and higher taxes).

Harnessing flood waters for irrigation and the nutrient-rich deposits is an activity replicated in many parts of the world, sometimes by artificially flooding areas of land (see RICE). Water meadows, once common to many areas of low-land England and elsewhere in Europe, are an

example of deliberate flooding of the landscape to improve pasture for grazing. Initially this was achieved by temporarily blocking a watercourse and causing it to overflow onto adjacent land (known as “floating upwards”), but later (from the seventeenth century onwards) this developed into sophisticated systems of sluices and channels that afforded better control and avoided harmful waterlogging (Smith and Stamper 2013).

Seawater is a less welcome intrusion for agriculture, although salt marsh has been used for grazing for centuries. More importantly, coastal areas, in particular where seawater ingress can be controlled, have been a focus for the production of salt often for millennia. Archaeological remains and deposits associated with salt production are frequent in many coastal areas; for instance, the “Red Hill” archaeological deposits found in coastal areas of eastern England are the result of prehistoric salt production.

Flooding is not always welcome and there is archaeological evidence for construction of flood defenses in Roman Britain (Jecock 2011) showing that, while the rivers and coast were attractive areas to settle, due to the transport links and other services they afforded, they also presented challenges. In North America, increases in flooding of the Mississippi have been correlated with the decline of occupation at Cahokia in the thirteenth and fourteenth centuries CE (Munoz et al. 2015). As well as being potentially destructive, flood waters can harbor diseases; for instance,

Figure 1 (Left) Flooding at East Lyng and Athelney, Somerset, England, showing the early medieval burh, causeway, and monastic complex as islands in the flooded landscape. Source: Photo D. Grady, copyright Historic England, published with permission. (Right) Rawda nilometer, Cairo. Source: Copyright John Cooper, published with permission.

the World Health Organization recognizes that malaria epidemics in the wake of flooding are not uncommon. Osteoarchaeological studies (see PALEOPATHOLOGY) have revealed evidence for malaria as a significant disease in medieval Europe in areas prone to flooding. Interestingly, the study of incidence of schistosomiasis (a condition caused by parasites associated with still water) in Egyptian archaeological populations suggests that it was the transition from reliance solely upon the natural flooding of the Nile to controlled irrigation techniques that contributed to the increase in prevalence of the condition (Hibbs et al. 2011).

Outburst floods are sudden flooding events resulting from the sudden failure of a barrier (natural, such as a glacial moraine; volcanic barrier; or human-constructed barriers, such as dams), usually of a lake or sea, resulting in a very sudden release of a huge volume of water. Such events suddenly and catastrophically change the landscape and are sometimes referred to as “mega floods.” Marine flooding is often of this type, particularly when it occurs as a result of storm surge (such as the catastrophic flood that affected the North Sea in 1953, killing thousands of people in the Netherlands, Britain, and Belgium), seismic activity (as suggested for the Bronze Age caldera-creating eruption of Santorini in Greece), or overwhelming of natural barriers. It is suggested that the breaching of the Dover Straits between what is now southeast England and northern France was the result of one such “mega flood” when the glacial lake in the area of the North Sea broke through a narrow chalk ridge, possibly as the result of an earthquake (Gupta et al. 2017). In recent history, such events have been associated with dam failures, although in the eighteenth century, catastrophic breach of a landslide barrier that had been created by earthquake on the Dadu River in Sechuan, China days earlier led to flooding over thousands of miles and the death of over 100,000 people (Dai et al. 2005).

Tsunamis are waves caused by a sudden displacement of water in a large water body, usually an ocean or lake, most often as a result of tectonic activity. The resulting waves can be extremely large and have a terrible impact, often causing widespread devastation and death far in land—as seen in the Boxing Day tsunami that hit the Indian Ocean in 2004. The word tsunami comes from

the Japanese for “harbor wave” and they have been particularly associated with Japan, with the islands having experienced a number of the most significant tsunamis of the past few hundred years (Enshunada Sea 1498, Ise Bay 1586, Nankaido 1707, Ryuku Islands 1771, Sanriku 1896, North Pacific Coast 2011, all predominantly affecting Japan and featured in the “Top ten most destructive Tsunamis in history” in *Australian Geographic* 2011). Researchers investigating a sea cave in Aceh, Indonesia have identified a depositional sequence providing a record of tsunamis stretching back 7,400 years—the most complete record of tsunami deposits ever recorded that has the potential to inform understanding of the impact of these events upon the inhabitants of the islands, and potentially further afield (Rubin et al. 2017).

There are references to significant floods in the myths and legends of several societies (e.g., Noah in the Middle East, Gilgamesh in Mesopotamia, the Sumerian King List, Manu and Matsya in India). The common references to floods in the Judaic, Sumerian, and Babylonian stories have led some to speculate that there may have been a catastrophic flood in the region that is the origin of all these stories. However, although archaeological evidence shows that flooding was a significant part of life in ancient Mesopotamia, there is no evidence to suggest a single region-wide catastrophic flood; “flood deposits” found at Ur by Sir Charles Leonard Woolley in the early twentieth century are not replicated at other sites in the region. The “Black Sea deluge,” the proposed catastrophic flooding of the Black Sea in the sixth millennium BCE, is also a source of controversy, not over whether the area was inundated with seawater from the Mediterranean (researchers agree that this did occur) but about whether the changes observed in the deposits were the result of gradual or sudden one-off flooding.

In some places, it may not be flood stories but place names that point to a flooded past. For instance, in England, names with “ey” on the end, such as Athelney and Romsey, denote an island (from the Old English *ēg*); indeed, Athelney lived up to its name in the severe flooding experienced in Somerset, England in winter 2013–14 when the settlement was visible as an island in the flood waters (Figure 1, left).

In many areas, the incidence of contemporary flooding is set to increase as the impacts of global climate change are felt and sea levels rise. This poses a challenge to the conservation of archaeological remains and historic structures that may be at an increased risk from flood-related damage such as erosion and water damage. In 2017, intense rains and flooding in Peru threatened to harm a number of archaeological sites and monuments, and similar concerns have been raised elsewhere. Coastal flooding is frequently associated with high-energy events, such as storm surge or tsunami, and is therefore often accompanied by other processes, such as erosion, that can also cause harm to archaeological sites and historic structures. In Britain, storm surge wave impacts have been responsible for some dramatic discoveries, including Skara Brae (Orkney, Scotland) which was revealed as a consequence of storm-related coastal erosion but is threatened by future inundation from similar events. Marine incursions also have an impact upon groundwater levels—increasing them as the lighter freshwater is pushed up by the heavier seawater to mean sea level and above. Therefore, as sea levels rise, low-lying coastal areas can become freshwater wetlands with brackish (water with higher salinity than freshwater but lower than seawater) areas around estuaries. Recognizing and understanding this in the archaeological record can help to interpret archaeological sites and past human activity that exploited the rich resources associated with such areas; however, it also affects the contemporary and future preservational context of archaeological sites.

Adapting to these changes in sea level and flooding risk presents a challenge. Constructing flood barriers to hold flood water back (or slow it down) is one approach; however, this can impact upon archaeological deposits and historic places, which might be disturbed or altered in the process. Another approach is to adapt buildings to the risk of flooding so that when they flood they can quickly recover. In this regard, traditional building techniques and materials (such as the use of lime mortars and plaster, solid timber, and stone) have been shown to be far more resilient and recover more quickly than many modern materials. In fact, we can learn from buildings such as the Bishops Palace

at Wells, England, which we know from historical records was constructed in the thirteenth century as resilient to frequent flooding. There is also an increasing interest in “natural” flood management techniques which involve working with natural processes or traditional land management practices to slow down the movement of water and decrease run-off. These techniques are most successful where consideration has been given to the history of the catchment and human activity associated with it.

Industrial archaeology particularly that related to water control and use and infrastructure can be threatened by flooding. There have been instances where historic bridges have been blamed for exacerbating flooding by restricting the flow of water, and even instances where historic bridges have been redesigned and rebuilt to alleviate this (e.g., Charminster, southwest England). Some concerns have been raised about the possible impact of modern flooding in areas with an industrial heritage that might release harmful materials (such as lead and zinc) into the water and wider landscape (see WATER POLLUTION). There has been particular consideration of this in historic industrial areas of England and Wales (e.g., Howard, Kincey, and Carey 2015).

Foraminifera

ALEJANDRO CEARRETA

Universidad del País Vasco UPV/EHU, Spain

Foraminifera are single-celled organisms (protists) that possess a hard test (shell) and preserve in the sedimentary record after death. This test is secreted by the cell and is mainly composed of agglutinated walls (detrital grains glued together with organic cement) or calcium carbonate (predominantly calcite). The test consists of a number of chambers that arrange in numerous shapes and sizes. Adult foraminifera range in size from less than 0.40 mm (planktonic forms) to up to 10 cm in width (larger benthic foraminifera). They are tolerant to a range of variables such as salinity, temperature, oxygenation, and organic and nutrient flux. Foraminifera are exclusively marine; most are benthic (living on or under the seabed) although a few genera are planktonic (floating in the water column). Foraminifera are among the most abundant and ubiquitous shelled organisms in marine environments. Their distribution ranges from the intertidal salt-marshes to the deepest ocean trenches and from the equator to the poles. They respond rapidly to environmental changes, and individual species indicate specific environments. For example, a strong relationship exists between the altitudinal distribution of modern benthic foraminiferal species and tidal levels. Transfer functions that quantify this relationship have provided a basis for the reconstruction of Holocene changes in sea level (see SEA-LEVEL CHANGE) at a very high resolution. These reconstructions are constrained by taphonomic factors such as reworking and differential dissolution, resulting in mixed assemblages, indicated by poor preservation and unusual assemblage structure.

Foraminifera represent several advantages in comparison to macrofaunal fossils (e.g., molluscs). For example, they present a higher density in marine sediments, and consequently much smaller sediment volumes are needed for a reliable assessment. They commonly have shorter

life cycles and populations therefore respond quickly to environmental changes. After reproduction or death a large part of the foraminiferal assemblage is preserved in the sediment.

Foraminifera can be extracted from sediments obtained from surface samples and cores (sample size of at least 50 cm³). Samples should be washed through sieves (minimum 63-μm mesh) to retain sand-sized grains and this residue dried. The retained foraminifera can be picked out by hand with the aid of a binocular microscope using reflected light (target number of 300 specimens). When large numbers of sand grains are present, foraminiferal tests can be concentrated using a heavy liquid, with the tests being floated off (Murray 2006). Identifications are based on type collections, descriptions, and photographs in foraminiferal manuals, which can also be obtained through online resources such as the World Register of Marine Species (www.marinespecies.org).

Benthic foraminifera have important archaeological applications. For example, as common microscopic components of many ceramics, they represent a potential tool for determining the provenance of archaeological ceramics and raw materials involved in ceramic production, as well as the reconstruction of ancient ceramic technology (Quinn and Day 2007). Thin sections represent the most convenient means of detecting their presence in ceramics. Biostratigraphical and/or paleoenvironmental interpretations of foraminiferal assemblages in archaeological ceramics provide a reliable means of determining the source of the raw materials used in their manufacture. Detailed knowledge of local and regional geology is a crucial part of all provenance investigations of archaeological ceramics. Furthermore, foraminifera have the potential to contribute to the understanding of ceramic technology. The presence of foraminifera of conflicting geological ages or environmental tolerances is interpreted as evidence for both clay mixing and the addition of temper. Ancient ceramics containing well-preserved foraminifera are considered to have been low-fired, and

DOI: 10.1002/9781119188230.saseas0628

samples with poorly preserved foraminiferal assemblages are assumed to have been subjected to a higher degree of firing.

Rosendahl, Ulm, and Weisler (2007) developed techniques of foraminiferal analysis to distinguish between natural and cultural marine shell deposits in coastal areas. Cheniers and beach ridges are natural shell deposits formed by oceanic processes above the mean high tide level. They contain a wide range of taxa representing all shell size ranges, from juvenile to adult, and often large quantities of fragmented shells, reflecting the composition of the source areas. In contrast, shell middens are accumulations of shells that have been selected from the environment by humans as food (see MARINE MOLLUSCS) and are therefore indicative of cultural processes. These large concentrations of shells date from about 8–7 ka onwards, although earlier deposits have been found in some coastal caves. However, different natural processes and anthropogenic activities can produce the vertical and horizontal mixing of both types of shell deposits. Foraminiferal density can be used to differentiate natural and cultural shell deposits, as they abound in natural deposits formed by marine processes (>1,000 tests/100 g of sediment), whereas foraminifera are rare (<50 tests/100 g of sediment) or absent in deposits formed primarily by shellfish collection.

Sea levels have been substantially lower than the present for most of human existence throughout the Quaternary. Since 18 ka BP, glacio-eustatic sea-level rise of 120 m has transgressed important shelf and coastal areas of the world, submerging numerous Paleolithic and Mesolithic sites. Several of the world's religions describe a legendary Great Flood in their literature, such as the story of Noah's Flood in the Judeo-Christian tradition. A few years ago, this biblical narrative was connected to the Black Sea area. Two different scenarios were proposed: an Early Holocene event caused by a catastrophic Mediterranean inflow at 8.4 ka BP that accompanied the Laurentide Ice Sheet collapse, and an earlier Late Pleistocene event brought on by Caspian influx between 17 and 14 ka BP after the Late Glacial Maximum. In both scenarios, rising post-glacial water abruptly filled the Black Sea and submerged the previously exposed shelf. Accordingly, early Neolithic farmers were flooded and forced to

move into the interior of Europe, carrying with them knowledge of farming as well as the memory of the deluge. Yanko-Hombach, Gilbert, and Dolukhanov (2007), using paleoenvironmental reconstructions (see PALEOENVIRONMENTAL RECONSTRUCTION) based on foraminiferal content from numerous sediment cores, together with other paleontological and archaeological evidence, found that the Late Pleistocene inundation was more substantial. However, there was no evidence to support any catastrophic submergence of prehistoric Black Sea settlements. Similar scientific methodologies have been applied in other areas of the world to study landscapes submerged by the post-glacial rising of sea level, for example Doggerland in the North Sea.

Ancient harbors and their natural surroundings contain rich geoarchaeological records, with information on human occupation and use of the environment, natural catastrophes (e.g., tsunami impacts), and regional tectonic activity. Coastal systems are characterized by a general sedimentary progradation since 7 ka BP, at the end of the Holocene marine transgression. High-resolution sampling of excavated sections and cores (see SAMPLING IN ENVIRONMENTAL STUDIES) allows a very precise reconstruction of coastal and harbor history using the temporal and spatial distribution of foraminifera. Foraminiferal geoarchaeological studies began in the 1990s at Caesarea Maritima, eastern Mediterranean, to investigate its harbor's Roman history (Reinhardt, Patterson, and Schröder-Adams 1994). Later, Marriner and Morhange (2007) observed a remarkable repetition in ancient harbor stratigraphy (the Ancient Harbor Parasequence), in terms of both its facies and temporal constraints, evidenced through the use of paleontological indicators, notably foraminifera and ostracods (see OSTRACODS AND CLADOCERANS). Modification of microfossil assemblages were caused by local anthropogenic activities and human use of the harbor basin as a waste depocenter over thousands of years (Irabien, Cearreta, and Urteaga 2012). Among the numerous ancient harbors characterized by distinctive foraminiferal assemblages, Portus (near Rome) is remarkable because it is partially buried beneath thick tracts of coastal and fluvial sediments related to the Tiber delta progradation (Di Bella et al. 2011).

Formation Processes

MATTHEW G. CANTI

Historic England, UK

Although some archaeological remains, notably artifact scatters and standing buildings, are found at the land surface, the majority are below ground, where cultural material deposited at or near the surface has then been buried. The term “formation processes” is widely used in archaeology to cover both the behavioral aspects of archaeological deposition and the natural or seminatural processes involved in burial and taphonomy. The behavioral aspects are covered elsewhere (see *BEHAVIORAL ARCHAEOLOGY*); this entry discusses how sites are buried, followed by the soil and groundwater processes by which they are disturbed or transformed.

Burial agents and processes

Water

Flowing water both erodes archaeological stratigraphy and buries it, sometimes both. Alluvial sites in wetter climates are often associated with paleochannels and well-preserved waterlogged material (see *Groundwater conditions* below), while those in semi-arid environments are characterized by high-energy rearrangement and rapid burial (Schiffer 1987). Erosion at coastal and shoreline sites can be extreme, but this also presents opportunities for exposure and excavation. Lake- and sea-level changes lead to very good preservation by rapid sediment covering, protection, and waterlogging. However, significant rises in sea level (see *SEA-LEVEL CHANGE*), especially the approximately 120 m post-glacial rise of the last 20,000 years, must have put large amounts of archaeological remains beyond current practical reach.

Wind

Wind can act as both an erosive and a depositional agent in a similar way to water. Suspended particles, entrained by high-velocity winds, act to sandblast upstanding structures in arid and semi-arid environments. The particles come to rest where the wind drops and deposits are therefore sorted by grain size. Loess is the name given to the silt-sized (grains of 2–63 μm) deposits, which, although occurring in deserts, are most widespread in periglacial areas, forming a northern hemisphere mid-latitude belt from China, through Europe, to the United States. Cover sands, sheet sand, or dunes are windblown sand (grains typically $>63 \mu\text{m}$) and are more characteristic of deserts, but localized deposits do occur in periglacial conditions.

Animals

Animal hooves can transport large amounts of soil when herds are driven over suitable surfaces. In addition, the dung and bedding of stabled animals will leave thick deposits where ashed (as in many Mediterranean caves) or preserved by desiccation. Some colluvium may also have animal origins, resulting from trampling action on slopes, but the major animal processes are disturbance rather than primary burial (see below).

Humans

Deliberate dumping of soil, building of earthworks, mining waste, manuring, and rubbish scattering are primary anthropogenic burial processes. Humans also collect, discard, and burn materials at or near habitation sites, producing waste dumps, shell middens, and ash mounds. Secondary site burial processes occur when earth is used as a construction material and then decays in situ. Topsoil has long been a construction material in North Atlantic cultures, and the use of adobe (see *ADOBE*) is widespread in the arid areas of the Americas. One of the most

striking examples of this process is the repeated mud-brick house collapse which forms tells in the Middle East.

Volcanoes

Ash, pumice, and lava can all bury archaeological sites and will often form datable layers between horizons in areas of regular eruption. Air-borne ash can travel long distances depending on wind conditions, but the most extreme events are pyroclastic flows, in which a fast-moving dense cloud of hot ash engulfs areas extending many miles from the original eruption site. These are the volcanic materials that buried Pompeii and Herculaneum in 79 CE.

Gravity

Natural rockfalls bury habitation sites near cliff faces and contribute to most cave sediments (see CAVES AND FISSURES). Colluvial accumulations are attributable to gravity (see EROSION) but will typically require human activity (e.g., deforestation) or climatic change (e.g., aridification) to promote the instability needed to produce substantial downslope movement. Large episodic accumulations are characteristic of the Mediterranean valleys (see Limbrey 1975).

Post-burial disturbance agents and processes

Animals

Numerous macro- to mesoscale organisms disturb the burial environment. Rabbits, badgers, gophers, packrats, prairie dogs, and foxes are all renowned for their burrowing activities, while ants, termites, and earthworms deposit fine material at the surface, causing some stratigraphic deflation and making finds sink into the soil (Canti 2003).

Plants

Rooting activity moves objects in the soil, but its effects are generally small. Tree throw by wind or human action is, however, an extremely

disruptive force whereby large root plates potentially enclosing well-preserved stratigraphy are lifted to a position partially above the ground surface, then rot away, re-depositing it in a new stratigraphic position.

Humans

Plowing and other forms of tillage cause massive disruption of archaeological stratigraphy where new ground is being broken. Thereafter, in situations of repeat cultivation, compaction from machinery wheels can lead to breakage of weaker objects such as ceramics and some bones (see Oxford Archaeology/Cranfield University 2010). Cultivation on slopes renews destruction by slowly lowering the land surface, bringing deeply buried material closer to the surface.

Ice

Freeze-thaw action on archaeological sediments causes numerous periglacial phenomena (cryoturbation), as well as disruption and patterning of finds. Flake dispersal experiments by Bowers, Bonnicksen, and Hoch (1983) in Central Alaska, for example, suggested that needle-ice and frost-heave combine to produce dispersal that could mimic human activity. Examples of archaeological stratigraphy being disturbed in this way are rare, however, probably because of the unsuitable conditions for habitation and a tendency for site destruction in periglacial environments (see GLACIAL AND PERIGLACIAL ENVIRONMENTS). Cryoturbation's major effect is to cause difficulties of stratigraphic interpretation when excavators are unfamiliar with the features it produces, such as the fine subsoil partitions associated with patterned ground in many northern European sites.

Post-burial chemical transformations

Once buried, sites and their artifacts undergo transformations dependent on the chemical make-up of the burial matrix, the ambient temperature, and the groundwater conditions. Ceramic and metallic objects are only mildly affected by these differences, with metals tending

to produce corrosion products that protect or engulf them under a range of environmental conditions. By contrast, preservation of biological materials and artifacts made from them (except where charred) is very much influenced by the burial conditions. At sites with extreme dryness or cold, and sites where the burial medium is unfavorable to life (e.g., the Halstatt salt mines), processes are slowed to a point where change is minimal over human or even millennial timescales and biological materials are frozen, pickled, or mummified. These conditions are either rare or poorly explored, and most archaeological sites are undergoing slow transformation by a complex interplay of chemical and physical changes.

Chemical make-up

The primary mineral make-up of the burial medium is key to any understanding of formation processes. Soil material formed chiefly of silica (sands, silts, some clays, and some volcanic ashes) tends to produce acidic (low pH) conditions when subjected to evapotranspiration surplus (where precipitation exceeds evaporation from the surface). The other main mineral components that commonly make up the bulk of the burial medium are calcium compounds—notably carbonate (limestone) and sometimes sulfate (gypsum), both of which are alkaline (high pH).

In acidic conditions, all the alkaline archaeological materials tend to dissolve, so calcium carbonate (most shells and shell artifacts) and calcium phosphate (a major component of bones and bone artifacts (see *BONES AND IVORY*)) will disappear. Preservation of organic materials such as wood and leather is usually better in acidic conditions, but other factors (particularly groundwater conditions; see below) may be more important.

Organic matter is the other major component of burial environments. It is mildly acidic in nature, but has little impact on pH by itself; it does, however, provide the fuel for microbially driven reduction processes (see *Groundwater conditions* below) which can result in strong acidification.

Temperature

Even at 50 cm down from the surface, mean annual soil temperature can be in the mid-20s (°C) in some tropical regions or down to below 0°C in periglacial areas. This range has a profound effect on the rate of transformations, but not the trajectory.

Groundwater conditions

In well-drained sites, where the groundwater table is below the archaeological remains, water from rainfall events is rapidly lost and the soil atmosphere returns quickly to oxygenated conditions. Under these circumstances, organic materials are rapidly decayed, and alkaline matter such as calcium carbonate (limestones and many shells), sulfate (gypsum), and phosphate (bone mineral material) are all slowly dissolved. Other compounds including calcium phosphate and calcium carbonate will sometimes precipitate under waterlogged conditions, and can impregnate or replace organic materials.

If, however, the drainage is locally impeded, gases move much more slowly through the soil and reduction can start to build up quite rapidly. Aerobic soil organisms which normally produce CO₂ from the breakdown of organic material can no longer thrive and are replaced by organisms producing methane (CH₄). This change slows the breakdown of organic matter and thus promotes preservation of some artifacts such as wood, textiles, and leather. In reduced soils, another important feature is that iron (Fe) compounds go into solution, accompanied by a change from the red or rust colors of Fe III (insoluble) compounds to the blues and greens of soluble Fe II. Brown and reddish sediments will therefore go blue or green and either lose their iron staining or have it redistributed as mottles and iron pans when drainage (and thus oxidation) is re-established. This is the process responsible for the iron deposition and associated drainage impedance in the South Scandinavian barrows (Holst, Breuning-Madsen, and Rasmussen 2001).

If a source of sulfate (SO₄ salts) is present in waterlogged sites, commonly as a result of seawater incursion at coastal locations, then a particular group of specialized microorganisms can metabolize the oxygen from the sulfate. This

process leaves reduced sulfur available in the soil water, and either hydrogen sulfide (H_2S) gas or pyrite (FeS_2) is created. The gas will disappear by diffusion out to the atmosphere, but pyrite can remain in the soil indefinitely or until oxygenated conditions are re-established. At this point, the pyrite oxidizes to sulfuric acid and iron oxides, producing very strong acidity which can be devastating for archaeological remains (see, for example, the destruction at Starr Carr recorded by Milner et al. 2011). In calcareous areas, the sulfuric acid will neutralize soil calcium carbonate, in which case gypsum (CaSO_4) is formed.

Process interactions

Processes have been discussed here in an ordered sequence of three phases. Clearly, however, real site histories can go through multiple iterations or have simultaneous processes ongoing at any one time. A site may be partially buried, waterlogged, dried out again, and reworked by soil organisms, then eroded or re-buried. Formation processes tend to repeat or remain the same in stable geomorphic or climatic situations, but the older the site is, the more processes can have operated as environments changed over the longer term.

FURTHER READINGS

Fruits, Vegetables, and Nuts

ALEXANDRA LIVARDA
University of Nottingham, UK

Definitions

From a botanical point of view a fruit can be defined as the ripened seed-bearing ovary (simple fruit) or ovaries from one or more flowers (aggregate and multiple fruits, respectively) of a flowering plant, although in some cases it also includes nonovarian tissue (accessory fruits, such as apples and strawberries). In this context, “nut” is a type of fruit (simple dry indehiscent) that does not open after ripening, retaining its seeds. Hazelnut and acorn are examples of botanically defined nuts, but almond, for instance, does not belong to this category and is classified instead as a type of fruit called “drupe”.

A “vegetable,” on the other hand, is a broader categorization that usually refers to all plants that include edible parts, although it commonly refers to their nonflowering parts, such as roots, tubers, stems, leaves, and buds. In culinary and cultural terms, however, the distinction between fruits, vegetables, and nuts is rather more abstract. Usually the sweeter edible fruit plants that can be eaten as a snack but are not normally part of the main meal are classified as fruits, whereas those that are more savory in taste are considered vegetables. Tomatoes and cucumbers, for instance, although technically fruits, in practice are thought of as vegetables. Similarly, whereas black pepper is a fruit in botanical terms, it is classified as a spice (see SPICES). In this framework, the term “nut” commonly refers to edible kernels that are enclosed in a hard shell. As food and taste are culturally subjective, definitions and approaches to such edible plants in the past would have varied both spatially and temporally. Acknowledging this potential bias, their definition adopted here will follow the modern cultural approach, while their study in archaeology needs

to take into consideration the context of their recovery in order to allow insights into their use and, thus, classification.

Recovery

The study of fruits, vegetables, and nuts in archaeology is traditionally part of the field of paleoethnobotany (see PALEOETHNOBOTANY), while palynology (see PALYNOLOGY), phytolith, charcoal, and wood analysis (see PHYTOLITH ANALYSIS and CHARCOAL AND WOOD ANALYSIS) can also add significant information on the presence, use, and management of these plants. Although certain parts of these plants, like the stones of some fruits and the shells of nuts, are large enough that they can be retrieved by the naked eye at archaeological sites, the recovery of macroremains of fruits, vegetables, and nuts in greater numbers and their systematic study can only be achieved by taking soil samples (see SAMPLING IN ENVIRONMENTAL STUDIES). Water-sieving and flotation are the most common recovery techniques used for the treatment of soil samples. In very arid areas, dry-sieving suffices for the separation of such plant remains from normally sandy contexts.

Preservation: cultural and taphonomic considerations

Seeds and other plant parts can be preserved in archaeological contexts under special conditions, most commonly in waterlogged (anoxic), very dry (anhydritic), or frozen environments, as carbonized through incomplete burning, and by mineral replacement of the organic parts when in contact with diluted minerals (see FORMATION PROCESSES). Mineral replacement is also common in species that generate mineral deposits resistant to decomposition, such as hackberry fruits that produce carbonates in their pericarp. In temperate and Mediterranean climates where waterlogging and carbonization (in the case of the latter) are the two major

forms of preservation, fruits and vegetables are predominantly preserved in waterlogged conditions, whereas nuts are commonly found in both preservation modes (e.g., Jacomet 2013).

This bias in the preservation of fruits and vegetables is the outcome of a series of both cultural and taphonomic factors. Fruit flesh and the edible part of vegetables, which are composed mostly of various soft tissues, do not preserve well under charring, and when they do, their identification is very difficult due to their usually fragmented nature and the general lack of diagnostic features (but see Hather 1993). Notably, vegetables are usually ready for harvest and consumption before setting seed, and it is these seeds that tend to be more readily preserved and easier to identify. In addition, fruits and vegetables do not normally come into contact with fire as part of their processing and preparation for consumption, reducing their chance of being preserved by carbonization. Nuts, on the other hand, can be roasted and their shells have few uses other than possibly fuel, so they are more likely to be burnt, thus increasing their chance of surviving as carbonized remains.

In arid, desert environments, fruits, vegetables, and nuts preserve very well, often retaining some of their original color, if somewhat darker and more brownish. An increase in the study of desiccated macroscopic plant assemblages, mostly from North Africa, has provided a glimpse of the breadth of material preserved and the impressive range of fruits and vegetables, among other food plants, used. Detailed paleoethnobotanical investigations—for instance at the two most important Roman trade ports on the Red Sea coast of Egypt, Berenike (e.g., Cappers 2006) and Myos Hormos, also a port in the Islamic period (Van der Veen 2011)—have revealed a lengthy list of food plants. In both settlements, fruits were the most numerous food plant group, highlighting the variety they added to the diet and their importance also as traded items.

Contextual biases and research questions

The contexts and sites in which fruits, vegetables, and nuts are usually found are dictated to a certain extent by their predominant preservation mode, which in turn impacts on the type of research

questions that can be addressed. Waterlogged preservation requires a high-water table and/or deep stratigraphy, which are usually encountered in long-lived settlements. Thus, good representation of fruits and vegetables occurs at certain site types, such as towns (see URBAN ENVIRONMENTS), and in particular parts of the world, such as in northern and central Europe. An interpretational issue posed by waterlogged (but also very dry) contexts that needs to be considered relates to whether the food resources, such as fruits and vegetables, have been deliberately deposited or form part of the natural vegetation. This is the case, for instance, for wild fruits, like various berries common across Europe that could grow as ruderals within and around settlements and are often found within paleoethnobotanical samples. In areas where sites lack deep features or where the archaeology lies above the permanent water table, for example at many rural sites, plant remains are found mostly in a carbonized state, and fruits and vegetables are normally underrepresented.

Mineral-replaced plant macroremains are mostly recovered from human fecal deposits, such as cesspits and garderobes, with fruits being among the most common such finds. In historic urban sites, such contexts are often associated with houses of the higher social class, providing a better understanding of the vegetative food sources of the wealthier part of the population.

The investigation of issues like food consumption and trade, dietary breadth, and arboriculture and horticulture thus needs to take into account all the potential biases in each preservation mode.

Origins, domestication, and use

Fruits, vegetables, and nuts have been important food resources, following the human trajectory since its very beginning. They have also been used for the production of beverages (e.g., wine), oils (e.g., sesame and olive oil), dyes (e.g., from beetroots and onions), even containers (e.g., gourds), for medicinal purposes, and as fodder, craft, and construction material. Gathered from the local environments, several of these plants became increasingly managed by humans, some eventually being fully domesticated, whereas others remained wild resources, at least until

recently. Acorns gathered from the wild, for instance, were one of the staple resources in many parts of the northern hemisphere, such as in California where archaeological evidence attests to the long time-depth of their use (Pearman 2005, 133–134). Ethnobotanical work has also provided some interesting insights into the complex nature of the relationship between hunter-gatherers and the vegetative world and the management of fruit and vegetable staples by these people. For instance, a traditionally major food source for many Aboriginal groups in Australia were yams, which although not domesticated were carefully managed. This was achieved by preserving certain sections in the areas in which the plant grew for future exploitation and by harvesting the plants in such a way as to remove the tuber but not the top part with the growing vine, ensuring production in the following seasons (Hynes and Chase 1982).

The origin of fruit, vegetable, and nut domesticates can be traced across different parts of the world, and for many still remains a matter of enquiry. Southeast Asia is a key region from which a great number of domesticated fruit species originated, such as banana and various citrus fruits. Olive (see OLIVES AND OLIVE OIL), grape (see GRAPES AND VITICULTURE), fig, and date palm formed the basis for the development of horticulture in the Mediterranean basin, with the first two occupying a central part in debates regarding, for example, the emergence of Aegean palatial societies. Apples and pears originated in temperate central Asia and similarly wild plum and walnut are thought to be native in temperate Eurasia. The most important fruits of African origin are watermelon and melon. The Americas, on the other hand, have contributed some key staple foods, such as the potato and tomato, which have shaped national cuisines and influenced socioeconomic changes around the world. Such an example is large-scale migration and social restructuring as a result of the potato blight disease in Ireland in the nineteenth century.

The domestication process of fruits, vegetables, and nuts is often very complex and the subject of on-going research that affords new insights into the socioeconomic networks of the people and cultures involved. Distinguishing wild from domesticated varieties, which provides valuable information for the early history of such plants, is often particularly difficult, and requires a

cross-disciplinary approach, with genetic studies and the increasing application of geometric morphometric analysis of archaeological and modern specimens proving particularly fruitful. Horticulture and arboriculture appeared in many parts of the world much later than agriculture, partly due to the higher financial and longer-term labor investment, and the more advanced techniques and tools needed for the cultivation of some of these species (see OLIVES AND OLIVE OIL). In Europe, the voyages of discovery and the emergence of “scientific” botanical gardens during the seventeenth and eighteenth centuries contributed significantly to the movement and emergence of numerous new varieties of fruits, vegetables, and nuts. Nowadays, the expansion of monocultures and the general reliance on a few genotypes of each species renders them more susceptible to disease and adverse climatic conditions. Research on these plants aimed at a better understanding of their “biography” is thus crucial not only for an in-depth appreciation of the interactions of people with their environment through time, but also for the development of improved varieties and sustainable use.

Glacial and Periglacial Environments

MARTIN R. BATES

University of Wales Trinity Saint David, UK

Introduction

Climates over the last 2.6 million years (during the Pleistocene or Quaternary) have fluctuated markedly and these shifts have resulted in periods of ice increase and decrease at mid to high latitudes and in the mountains. In high-latitude regions, this has resulted in shifts between colder episodes (glacials), during which ice cover may increase, and warmer episodes (interglacials), with reduced ice cover. Within the cooler episodes, periods in which ice sheets and mountain glaciers expand (glaciation) tend to be relatively short (although they do have a significant impact on the associated landscapes). Much of the time during these cooler episodes is characterized by lower temperatures, reduced sea levels, and altered vegetation patterns, but with little or no glaciation except in upland areas. In many respects, these conditions represent the “norm” between the extremes of the glaciated landscape and the short-lived interglacial episodes.

The term glacial is derived from the Latin “*glacialis*” meaning cold or frozen; the term periglacial refers to an area adjacent to a glacier or ice sheet subject to repeated freezing and thawing. This term was coined by the Walery von Lozinski, a Polish geologist, in the early twentieth century. Today the term is used to refer to nonglacial processes and features of cold climates (André 2009) that may or may not occur in proximity to glacial ice.

Glacial environments

The expansion of ice through mountain regions as glaciers and across lowland areas as ice sheets has left a distinct suite of features for geologists and geomorphologists to decipher. These vary from erosional features such as striations on rock (Figure 1a) and ice-molded bedrock (such as stoss-and-lee forms and roches moutonnées) to depositional features such as till (Figure 1b) moraines (debris from melting ice), eskers, and drumlins (linear or mound-shaped deposits of sand and gravel deposited during glaciation). Generally, processes associated with glacial environments are detrimental to the preservation of archaeological remains and no evidence is currently available to indicate that humans were active in such extreme environments until, perhaps, the Holocene.

Glacial environments and glacial activity have been important in changing landscape structure and modifying features of the pre-glacial environment. For example, a catastrophic collapse of a pro-glacial lake in the southern North Sea during Marine Isotope Stage (MIS) 12 times eroded a major channel through the chalk downland connecting southern England with northern France (see FLOODING). This process created the English Channel and resulted in Britain becoming an island in the subsequent interglacial when sea levels attained levels close to those experienced today (Gupta et al. 2017). This glacial activity also blocked the course of the River Thames into East Anglia and diverted it southwards into its modern channel (Gibbard 1985), creating the modern geography of southern England.

Glacial activity has been responsible for the burial and preservation of some important geological and archaeological sequences. For example, around the Norfolk coast in eastern

Figure 1 (a) Ice-striated rock surface near Llyn-y-Gadair, Cader Idris. (b) Till deposited by ice at Happisburgh, Norfolk during the Anglian glaciation of eastern England. (c) Coarse-grained gravels deposited by braided channels during cold climate conditions at Stanswood Bay, Hampshire. (d) Complex cold-stage deposits at Cagny-la-Garenne, Somme valley. Loessic sediments are present at the top of the profile and are underlain by soliflucted gravels. (e) Ice wedge cast from Covehithe, Suffolk.

England, glaciation in MIS 12 buried the important Cromer Forest Bed sediments that contain not only important faunal and floral records of Middle Pleistocene environments but also the tools and footprints left behind by northwest Europe's earliest occupants (Ashton et al. 2014).

Periglacial environments

The term periglacial environment is used here in its broadest form and encompasses a wide range of climatic conditions, ranging from the earliest evidence of global cooling following an interglacial, through to full glacial conditions. In northwest Europe these conditions result in a range of different environments developing. They are associated with lowered sea levels (see *SEA-LEVEL CHANGE*), river systems (see *RIVER SYSTEMS*) transporting coarse-grade

sediments (Figure 1c), vegetation shifted towards grassland-dominated ecosystems, and faunas associated with herd-dominated species such as reindeer, horse, and mammoth. Permafrost (deeply frozen ground) may characterize parts of the cooler climate cycle. Reconstructing these environments has been possible because of a wide range of environmental indicators (beetles, molluscs, small mammals, and plant remains) which are often preserved within fluvial or lacustrine sediments associated with these landscapes.

A range of sediment types and geological structures provide scientists with evidence for these cooler conditions. Sediments include the wind-blown loess found extensively in northwest Europe (Figure 1d) as well as across large parts of Eurasia. Milder climatic episodes within these cool episodes may be indicated by the presence of paleosols within the loess (Figure 1d). Sediments characteristic of seasonal melting of

permafrost include solifluction deposits (debris flows of typically unsorted sediments downslope during spring melts (Figure 1d)). Features developed within sedimentary units may also be indicative of frozen ground conditions in the past, for example, ice wedges (Figure 1e). Other depositional systems also attest to cooler conditions. River systems tend to carry coarser loads (Figure 1c) during spring and summer thaws while occupying the multiple channels of a braided channel system.

Archaeologically, periglacial landscapes are important as environments in which Paleolithic populations, at least as far back as the Middle Paleolithic, once thrived (Pettitt and White 2012). Climate cooling associated with these cooler events that resulted in the expansion of ice sheets and lowering of sea levels opened large areas of the continental shelf to colonization by plants and animals (Gaffney, Fitch, and Smith 2009). These landscapes are known to have been used by humans, including Neanderthals (Tizzard, Bicket, and De Loecker 2015), during the Middle Pleistocene. Elsewhere, sediments deposited under periglacial conditions, such as the sands and gravels of the major river systems, contain rich archives of stone tools swept from the occupied landscapes into the rivers. These records form rich archives for Paleolithic archaeologists (White 2016).

Grapes and Viticulture

SOULTANA MARIA VALAMOTI

Aristotle University of Thessaloniki, Greece

Grapes, the fruit of the grapevine *Vitis vinifera*, have been consumed by human societies in Europe, the Mediterranean, and western Asia since ancient times, either freshly harvested or transformed through the course of time into various forms of food and drink, as well as medicines (e.g., Galen's medicinal wines), perfumes, and ointments (see **PERFUMES AND COSMETICS**). Originally distributed in its wild form in areas spreading from the Caspian Sea to the western Mediterranean (Terral et al. 2010), cultivation introduced the grapevine to many parts of the world. Wine, the produce *par excellence* associated with grapes and viticulture, due to its mind-altering properties (see **DRUGS AND PSYCHOTROPICS**), would have generated sensory experiences enhancing the mnemonic power of the event, be it rituals and festivals among Bronze Age Hittite elites, symposia and religious festivals honoring Dionysus in ancient Greece, wedding feasts such as that of Cana, or "brainstorming" among officials of ancient Persia, reported by Herodotus. Such occasions could have enhanced a sense of belonging or underlined social distinctions. More mundane uses of wine include the ancient Greek breakfast (cereal rusks soaked in wine ἀκράτισμα), culinary uses in sophisticated recipes recorded by Athenaeus, and wine served in Roman (*popinae*) and Byzantine taverns.

Wine holds a significant position in archaeological discourse on social stratification, elite emergence, feasting, and trade. Textual and pictorial evidence underlines the luxury nature of wine among Bronze Age societies. Wine has often been considered a key factor in the emergence of Bronze Age elites, among the Sumerians, Egyptians, Minoans, and Mycenaeans in the Near East and the Aegean (McGovern, Fleming, and Katz 1995) (see **BEVERAGES**). In other parts of Europe, to the north and northwest,

during the Iron Age (approximately 800–450 BCE), wine, together with serving and drinking paraphernalia, seems to be a means of elite distinction among beer-consuming cultures, with impressive finds unearthed at sites such as the princely burials at Hochdorf and Vix (Dietler 1996). Seen from the wine-consuming countries' perspective, beer, on the few occasions it is mentioned in the literature, was regarded as the "barley wine" of foreigners. Archaeological science offers various means of detecting and pinpointing the origins of grapevine cultivation and wine making, methods that have evolved over the years opening up an array of potential for future explorations.

Paleoethnobotany (see **PALEOETHNOBOTANY**) offers direct evidence for the use of grapes: remains of grape pips, stalks, and fruit have been unearthed from archaeological habitation deposits under waterlogged, charred, mineralized preservation conditions (see **FORMATION PROCESSES**). Although sporadic finds of grape pips form poor evidence for grape consumption, large quantities of pips and/or pips with grape skin, known as grape pressings, and whole fruits, corresponding in most cases to raisins, leave no doubt for the systematic harvesting of grapes and their drying for later consumption of the fruit or their pressing for the extraction of grape juice. Early grape pressings are known from a burnt Neolithic house at Dikili Tash in northern Greece dated to 4300 BCE (Valamoti et al. 2007), while whole raisins are reported from an Early Bronze Age (2900 BCE) room at Tell es-Sa'idiyeh in the Jordan valley (Cartwright 2003). Experimental archaeology (see **EXPERIMENT IN ARCHAEOLOGY**) has contributed significantly towards the distinction of the different grape products in the paleoethnobotanical record and the distinction between wild and domesticated pips (Cartwright 2003; Smith and Jones 1990).

The mere presence of grape finds in the archaeological record does not suffice to suggest cultivation and domestication (see **DOMESTICATION**), as grapes can be harvested from wild female plants. Remains of *V. vinifera* charcoal (see **CHARCOAL**

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

© 2018 John Wiley & Sons, Inc. Published 2018 by John Wiley & Sons, Inc.

DOI: 10.1002/9781119188230.saseas0270

AND WOOD ANALYSIS) could suggest pruning and therefore cultivation of the grapevine, detected around the 3rd millennium BCE in western Asia (Miller 2008). The palynological record (see PALYNOLOGY) offers an additional analytical tool in the quest for ancient viticulture: the appearance or increase in *Vitis* pollen in long sequences provides strong indications for grapevine cultivation (Bottema and Woldring 1990).

Paleoethnobotany provides a means to recognize grapevine domestication, and therefore cultivation in the archaeological record, on the basis of grape pip measurements. Typical domesticated grapevine characteristics include elongated pips with long stalks and a greater length to breadth ratio, based on observations on modern pips (Mangafa and Kotsakis 1996). Inferring the timing of viticulture is, however, a difficult task, as some cultivated varieties possess morphologically wild pips. Wild-looking pips dominate Neolithic finds; nevertheless, recent morphometrics show that well into the historical period, when systematic viticulture is known from textual evidence, wild-looking pips continue to be present in the paleoethnobotanical assemblages (Terral et al. 2010). Grapevine cultivation involved the vegetative reproduction of grapevines selected for color, aroma, and/or sweetness of the grapes, a process culminating in special wines of the ancient world such as Greek Thasian and Roman Falerian wines, an early form of “denomination of *origin*.” Early attempts to manage the plant and select for and propagate particular individuals led to viticulture that was geared towards increasingly large production levels, well beyond the potential of wild plants and usually associated with wine production.

The paleoethnobotanical record shows that despite earlier inferences for a single origin of viticulture, in the Caucasus or the Near East, multiple origins in the wider area of the plant’s natural distribution are a more likely scenario, rooted already in the Neolithic (Valamoti et al. 2007). This insight is supported by modern and ancient DNA studies of grape pips (Manen et al. 2003) and morphometrics (Terral et al. 2010) which show variability in ancient grape populations corresponding to different varieties. It is also in agreement with the multiple mythological origins of the ancient Greek wine-god Dionysus,

including Phrygia in the Near East, the Aegean, Boeotia, and Thrace.

The archaeological identification of ancient wine making is closely connected to discussions related to the origin of viticulture. Yet, viticulture is not a prerequisite for wine making. Early wine making in the archaeological record can be inferred through paleoethnobotanical remains (pressings of grapes indicating juice extraction) and residue analysis (see ORGANIC RESIDUE ANALYSIS) of pots potentially intended for wine. These methods have enabled the detection of tartaric acid/tartrate, succinic, malic, and citric acids on sherds from sixth century BCE Lattara (gas chromatography–mass spectrometry (GC-MS), ultra-high performance liquid chromatography (UHPLC) coupled with tandem MS, UHPLC-MS/MS; McGovern et al. 2013); maldivin (LC-MS) on sherds from Areni-1 Cave (4000 BCE) in southeast Armenia (Barnard et al. 2011); and tartaric, malic, syringic, and succinic acids from sherds from a Neolithic house interior at Dikili Tash (4300 BCE; Garnier and Valamoti 2016), to mention but a few. Besides wine, grape juice (must) could have had other culinary uses—for example, for the preparation of vinegar, a reliable preservative in antiquity, or of a condensed grape syrup, known as *ἐψημα* and *sapa* in the Greco-Roman world, still surviving in modern Turkey and Greece (*pekmez*, *πετιμέζι*). Unfortunately, such alternative preparations, also containing tartaric acid, are largely ignored in interpretations of residue analyses and wider discussions of early wine making, with few exceptions (e.g., Valamoti et al. 2007; Barnard et al. 2011).

Pottery provenance studies, including ceramic thin sections (see CHARACTERIZATION OF CERAMICS) combined with numerous finds of wine amphorae and seals unearthed across the Mediterranean offer further archaeological evidence for viticulture, wine production, and wine importation to nonproducing territories. The colonization of the western Mediterranean by the Greeks and Phoenicians was a trigger leading to the introduction of viticulture and wine making in the western Mediterranean around the sixth century BCE. Thus, from the cradle of viticulture in western Asia and the eastern Mediterranean, the cultivation of the grapevine not only spread westwards, but also took off in these new lands

in later times, with French wines, not Greek or Levantine, holding a worldwide reputation nowadays. The Romans spread viticulture further through their conquests, while the eastwards spread of the grapevine to China appears to have taken place around 2,400–2,000 years BP, evidenced by paleoethnobotanical finds from funerary contexts at Shengjindian, Xinjiang, and Yanghai (Jiang et al. 2015).

Archaeological science, through the combination of paleoethnobotany, morphometrics, ancient DNA studies, ceramic residue analysis, and pottery thin sections, has made considerable steps towards the investigation of grapevine exploitation in the Ancient world, from prehistory to later periods, as well as of the circulation of wine through ceramic thin sections in antiquity as well as in later times. Future paths of investigation include further elaboration of the methods employed for detecting ancient wine, a better understanding of the evolution of domestication, and the development of different varieties through a combined use of morphometrics, experimentation, and broadening of the paleoethnobotanical datasets investigated. An integrative approach combining archaeological science with artifactual evidence and archaeological context, as well as textual sources, compared with similar data over large spatiotemporal scales, hold the key to revealing regional patterns in food choices related to grapes and wine in the ancient world.

Hydrological Modeling

KAI WELLBROCK

Lübeck University of Applied Sciences, Germany

Most archaeological research eventually leads to a consideration of water supply for the ephemeral, seasonal, or permanent camps and settlements. Therefore, integrated hydrological research and concepts are becoming increasingly important for better understanding of past societies.

Archaeological investigation of hydraulic structures may provide data not only about horizontal and vertical stratigraphy, construction techniques, function, and use, but also about the date of features and how different occupation sites relate to each other. Whole systems can better be understood through comparative study, taking into account that interregional migration and exchange networks would have involved the transfer of hydrological and hydraulic competencies. Often hydraulic engineering was focused not only on supplying drinking water but also on more sophisticated and pleasurable aims such as providing water for fountains, water gardens, bathhouses, and the like. Such systems were often developed to improve public hygiene and living conditions as well as for entertainment.

Understanding water supply and water catchments in arid environments is particularly important, as in these regions water availability is often a limiting factor, affecting both seasonally and permanently occupied sites. Water scarcity becomes even more important when we consider the high variability of water resources in the desert margins of arid lands which is highly dependent on climatic preconditions.

Generally, and from a technical perspective, hydrological modeling in archaeological context, that is, archaeohydrology, aims to reconstruct human/cultural water utilization and drainage in the past. It may relate to tangible spheres, for example archaeological findings of specific hydrologic catchment area, or it can deal with

past human behavior or with water resources in general. In scientific terms, archaeohydrology provides quantified data about water resources and their use, and analyzes or identifies different types of water management strategies, taking social structures and economic parameters of archaeology into account (Wellbrock, Grottker, and Gebel 2017).

Archaeohydrological research involves the application of a whole range of different methods including archaeology/cultural anthropology, archaeobiology, geoarchaeology (see GEOARCHAEOLOGY), geomorphology (see GEOMORPHOLOGICAL SURVEY), and environmental sciences, including hydrology. From a hydrological point of view, archaeohydrological research should follow a three-stage process or agenda: identification, quantification, and utilization. Of course, these aspects need not follow a strict sequence, with different parameters playing a recursive and iterative role in the various contexts of analysis.

Archaeohydrology has strong links to paleohydrology, which aims to reconstruct past channel patterns, river floodplain, alluvial chronology, and so on (Gregory and Benito 2003; Baker 2014). The main difference between these disciplines is that paleohydrology focuses on the natural environment and archaeohydrology considers artificial and technical measures and how those manipulate the natural water cycle. Also there are strong links with geoarchaeology, geomorphological and sedimentological research (reconstruction of cultural and natural landscapes, and land use), and biological research (e.g., palynology (see PALYNOLOGY), paleoethnobotany (see PALEOETHNOBOTANY), zooarchaeology (see ZOOARCHAEOLOGY), physical anthropology, and the various isotope analyses).

As a first step in an archaeohydrological investigation, if possible all water resources should be identified for the location being investigated. In addition to surface runoff, groundwater is often the basis of water supply for ephemeral, seasonal, or permanent occupations. In particular in arid to semi-arid environments, the type of

water resources present and the probability of their combined use have a major influence on the reliability and availability of water. Remote sensing (see AIRBORNE REMOTE SENSING) and meteorological data as well as topographical and geological maps are prerequisites in helping to identify local water resources. Next, a preliminary interpretation of hydraulic installations at each site will help to identify the type of water resource used. Geophysical prospection, that is, mainly electrical resistivity tomography (see ELECTRICAL RESISTIVITY), may provide information about local hydrogeology and the abundance of shallow aquifers. As well as such technical or scientific information, archaeological evidence is useful for revealing functional aspects of water use in the past local environment. Even reference to the environmental knowledge of present-day inhabitants may provide valuable information for the interpretation of past environments, and water resources and their utilization.

Once the different types of water resources have been identified, hydrological models can provide quantitative data on the amount of water available perennially, seasonally, ephemerally, spatially, and so on. The types of models used can be manifold. In general, these comprise both surface runoff models and groundwater models. Water balance models, which consider equilibrium between water demand and supply, can also be useful. If necessary and possible, a combination of different models should be employed. The range of models applied in this step may vary from very simple empirical ones to more detailed numerical models. The type of model depends on the site/location/region itself and on the question posed.

For the calibration of any hydrological model, data are needed that represent the local/regional preconditions. Principally, in-field measurements of parameters such as infiltration capacity and groundwater recharge are necessary. Additionally, remote sensing data (elevation, meteorological data, etc.), geological data (type and spatial distribution of aquifers and aquifuges), and topographic data (land use, land cover, vegetation) are required (Harrower 2010). This calibration is the most difficult part of the modeling process.

Water sampling to determine the main ions and isotopes present may be helpful for evaluating sources of water as well (Leibundgut, Maloszewski, and Külls 2009). Such investigations may indicate if (fossil) aquifers are laterally fed by shallow aquifers or interflow (e.g., in wadi beds). Therefore, this type of analysis can assess water reliability. Moreover, dissolved carbon dioxide can be used for radiocarbon dating (see RADIOCARBON CALIBRATION AND AGE ESTIMATION; Leibundgut et al. 2009). If aquifers are accurately located, near-surface long-term water-level monitoring can be useful to ascertain seasonal and spatial water abundance as well as allowing for calibration of groundwater models. The combination of calibrated hydrological models with proxy-data and paleohydrological and paleoenvironmental reconstruction (see PALEOENVIRONMENTAL RECONSTRUCTION) is also possible.

Finally, the interpretation and functional reconstruction of hydraulic installations (e.g., canals, dams, wells, cisterns, troughs) can provide a more profound understanding of water use. Therefore, this step is essential in interpreting the hydraulic installations found during archaeological excavations or surveys. Moreover, the approach should aim to both reconstruct the water management system as a whole and interpret single features or findings.

In addition to archaeological excavation, geophysical prospection, including magnometry (see MAGNETOMETRY) and surveys using ground-penetrating radar (see GROUND-PENETRATING RADAR) can be helpful for the reconstruction of whole systems. This is especially the case when geophysical findings are verified through ground-truthing. The mapping of any surface remains related to the system to be reconstructed is also necessary, and topographical survey is essential for determining drainage patterns and directions of water flow.

Single features or whole systems can be represented by technical models usually linked to methods of hydraulic engineering. For instance, the flow capacity of a canal can be estimated by simple empirical equations, for example, if there are markers indicating water levels. Such markers may consist of calcareous sinter deposits which

are formed due to turbulences when carbon dioxide is degassed from the water. Sinter deposits themselves may provide data about operation times and water sources (Sürmelihiindi et al. 2013). Diatom assemblages (see DIATOMS) may indicate velocity or depth of flow, general flow conditions (flowing or standing water), and even the water quality.

If the system to be reconstructed is more complex, numerical models are necessary. Such models may comprise two-dimensional water-level simulations for different operation modes. The output of such models will help in understanding the general layout of the system and the water management strategies employed, and finally foster ideas regarding overall water resource management.

For the reconstruction of horticultural or agricultural regimes, a plant–water–soil model is helpful. Such models not only consider the amount of water needed by the plants, but also take meteorological data (precipitation, evaporation) and soil properties (field capacity, grain size distribution, and thickness of several layers) into account. The outcome of such modeling may suggest a potential schedule of irrigation as well as help quantify the amount of water needed to sustain the regime. Generally, modeling plant–water–soil interaction will help to clarify which operation mode is possible or most likely.

Of course, for reconstructing horticultural systems we need to know which type of plants were grown, since they have major impact on the local water balance and therefore on the amount of water needed. Thus, such research has strong links with geoarchaeology and paleoethnobotany (see PALEOETHNOBOTANY) (Engel et al. 2012). Pollen or phytolith analyses (see PHYTOLITH ANALYSIS) can also help to identify plant remains in the sedimentary environments being studied. Geomorphological methods provide data about soil genesis and environmental factors, and are useful as proxy-data for paleoclimate and paleohydrology. Furthermore, dating sequences by means of conventional radiocarbon dating (see RADIOCARBON CALIBRATION AND AGE ESTIMATION) or optical stimulated luminescence (OSL) (see DATING AND OPTICALLY STIMULATED LUMINESCENCE) help to set up local chronologies for horticultural

practices and the technical systems used at sites.

Aside from functional information, the reconstruction of water supply and management regimes can tell us about water consumption by humans, plants, and livestock, as well as provide information on hygiene, leisure pursuits, and human behavior and how all these are interlinked with—or help the interpretation of—anthropological findings and data.

Lake Deposits

NEAL MICHELUTTI and JOHN P. SMOL

Queen's University, Canada

Paleolimnology is the study of lake sediments to obtain a long-term perspective on environmental change. The intellectual roots of paleolimnology extend to numerous disciplines with diverse aims. Given its ability to shed light on human–environment interactions, paleolimnology offers a powerful addition to archaeological research that cannot be fully realized by solely examining ancient artifacts or cultural remains. The blending of these two fields of study is a natural fit as paleolimnology can track the presence and impact of ancient societies on local environments, as well as reconstruct past climatic conditions or other environmental changes that may have contributed to cultural expansion or collapse.

Archaeologists have incorporated lake sediment studies into their research, even during the formative years of paleolimnology. For example, Patrick (1938) examined diatoms (see DIATOMS) from an archaeological excavation site in New Mexico containing the remains of mammoths and other megafauna. Changes in diatom assemblages from varying layers over time reflected changing salinity conditions, which corroborated changes recorded in faunal remains.

Despite the potential of lake sediment research to archaeology remained largely underutilized for many decades. This began to change during the late-1960s when researchers started shifting their focus from reconstructing cultural histories to considering the wider cultural landscape and the environmental factors influencing the rise and fall of early societies. This new research direction, commonly referred to as the “ecological approach,” also occurred at a time of advancements in paleolimnological methods, particularly in coring techniques (see CORING) and determining accurate sediment chronologies. It was during this time that the partnership of

archaeology and paleolimnology within projects became more common.

Tracking ecological impacts

The early applications of paleolimnology to archaeological studies typically focused on tracking the impacts of earlier societies on the environment. For example, Cowgill and Hutchinson (1964) analyzed the sediments of Lago di Monterosi near Rome to document the activities of the Roman Empire in this region. Using chemical analyses of the sediment profile, they showed that the Romans cleared the shores of the lake and frequently burned vegetation in a likely effort to prevent ambush from a road that ran adjacent to the lake.

In the Canadian Arctic, researchers used paleolimnological approaches to document how whaling activities of Thule Inuit nearly 800 years ago altered aquatic conditions and left distinct biological and biogeochemical signatures in pond sediments (Douglas et al. 2004). The Thule culture (ca. 1200–1600 CE), which preceded the Historic Inuit, were skilled maritime hunters and capable of killing bowhead whales from large skin-covered boats. The nutrients released from slaughtered whale carcasses enriched nearby oligotrophic ponds, which resulted in marked ecological changes including shifts in the species composition of diatom algae and the enhanced growth of aquatic mosses. Coincident with the ecological changes, the pond sediments record an enrichment in stable isotopes of nitrogen ($\delta^{15}\text{N}$), a proxy often used to track marine-derived nutrients as $\delta^{15}\text{N}$ is enriched in higher trophic levels (such as whales and seals). This study documented the earliest form of “cultural eutrophication” from Canada and the United States.

Tracking past cultural activities

Among the most common proxies used in paleolimnology to track human presence are pollen and charcoal from agricultural activities. One

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0338

of archaeology's long-standing mysteries is what happened to the Rapa Nui on Easter Island. Although there is still no consensus on what caused sociopolitical changes on the island, sediment core data provide valuable paleoenvironmental information on human–environment interactions. Pioneering lake sediment research by Flenley et al. (1991) indicated that, prior to human arrival, the island was forested or at least partly forested. The dominance of *Palmae* pollen in the sediment core, dating back prior to human arrival, indicates a forest dominated by palms, which is in stark contrast to the grassland ecosystem found on the island today. Charcoal horizons in sediment cores provide the timing for burning and initial forest clearance by Polynesian farmers, which began around 1000–1200 CE. Around this same time, there is evidence for increased soil erosion, and pollen data suggest that herbaceous species began to replace the initial palm-dominated forests, although forest clearing did not occur at the exact same time and rate in different parts of the island. Anthropogenic burning is widely considered the main reason for deforestation of the island (Rull et al. 2013); however, climate-related factors such as droughts have also been suggested as a factor in deforestation.

Pollution signals archived in lake sediments are another method that can be used to track past human activities (see WATER POLLUTION). For example, in South America, archaeological investigations surrounding the history of metallurgy have been hampered by extensive looting of metal artifacts. Analyses of metals (Ag, Bi, Pb, Sb, and Sn) in a sediment core recovered from a lake adjacent to the largest silver deposit in the Bolivian tin belt reveal that precious metal smelting in southern Bolivia occurred several centuries earlier than previously believed (Abbot and Wolfe 2003). Elevated metal concentrations in the sediment core dating to the early eleventh century CE suggest that scarcity of pre-Incan silver artifacts is not due to a limited ability to locate, extract, and refine silver ores. Rather, any artifacts from this time period were likely looted or recycled and transported elsewhere both before and after contact by Europeans. The metal pollution signal in the lake sediments thus provided evidence for a major pre-Incan silver industry, which would have otherwise remained

unknown due to the scarcity of metal artifacts from this time period.

Directly measuring human presence

Sediment cores can also contain microartifacts, or remnants, of prior human occupation. Although the recovery of submerged, intact cultural artifacts is rare, researchers have found that microdebitage—microscopic stone fragments (< 1 mm) generated during tool production—can be easily extracted and identified in sediment cores taken near tool-making sites. For example, researchers employed microdebitage analysis to identify a Late Paleoindian–Early Archaic-age tool-manufacturing site in the eastern Great Lakes region of North America (Sonnenburg, Boyce, and Reinhardt 2011). This method has strong potential to identify submerged historical sites, which is difficult because of their scarce nature and the rapid burial they experience in lacustrine environments.

In the absence of physical remains of archaeological artifacts, the unequivocal evidence of anthropogenic activity can still be detected using distinct biogeochemical compounds archived in lake sediments. Fossil biomarkers preserved in sediment cores continue to be developed to provide information on past human activities, including cultivation and pastoral activities and subsequent environmental effects such as biomass burning, vegetation shifts, and soil erosion (see ENVIRONMENTAL MANAGEMENT WITH FIRE; EROSION; and PALYNOLOGY).

One of the more promising indicators is fecal biomarkers, which can detect the presence of prior human and other animal activity. Feces from different species of vertebrates have variations in their contents of specific steroids due to differences in diet, ability to generate endogenous steroids, and the presence/absence of different anaerobic gut bacteria (Prost et al. 2017). Human feces, for example, have high concentrations of coprostanol, whereas herbivores have higher amounts of 5 β -stigmastanol relative to coprostanol contents. Researchers used fecal sterols from lake sediments in northern Norway to document the first occupation of humans and their livestock over 2,000 years ago (D'Anjou et al. 2012). The human activity could be subsequently

linked to an increase in landscape fires and a decline in woodland, which helped disentangle the effects of anthropogenic versus natural factors on the environment. Similarly, in the Canadian High Arctic, epicoprostanol (which has a distinctive presence in human sewage and in animal waste not endemic to the Arctic such as pigs, poultry, and magpies) has been used as a sediment biomarker to detect ancient human activity (Cheng et al. 2016).

Environmental reconstructions

Climate, the environment, and human culture are inextricably linked. Paleolimnological records can complement archaeological studies to provide a holistic picture of environmental and climatic conditions under which past societies burgeoned and collapsed. Nowhere, perhaps, is this better exemplified than on the Yucatan Peninsula where scientists have used sediment records to explore climate–environment interactions and ancient Maya society since the late 1950s.

Pollen records from sediment cores in the Maya Lowlands indicate the disappearance of a tropical forest occurring more than 3,000 ^{14}C years BP, which generally coincided with the expansion of Early and Middle Preclassic Maya populations. Traditionally, it was viewed that human activities were largely responsible for the forest decline and any climatic influence was negligible, but later research showed that climatic drying may have also played a role (Brenner et al. 2002). Likewise, researchers have shown a link between drought conditions and sociopolitical evolution in the southern Maya Lowlands. Using hydrogen and carbon isotopes of plant wax lipids preserved in lake sediment cores, Douglas et al. (2015) showed that relatively wet and stable conditions during 700 BCE to 200 CE were marked by continuous growth and increasing sociopolitical complexity, including the rise of large population centers, writing, and public monuments. Dry conditions, beginning ca. 800 CE, coincided with a decline in political complexity, including the end of monument building and written inscriptions and the cessation of centralized kingship (the main political entity of the Southern Lowlands for the first millennium CE). This political decline was not followed by any new, resilient political

centers, which led the researchers to conclude that the lack of any recovery in the Southern Lowlands was due to sustained drought conditions.

In summary, paleolimnologists have a long record of successfully reconstructing past environmental conditions that may be especially relevant to archaeologists (e.g., temperature fluctuations, drought cycles). Equally, they have a long record of reconstructing the effects of past human activities on ecosystems, which may provide important data and insights to archaeological studies. Paleolimnological data still represent a largely unused resource for archaeologists, but many new collaborative efforts are now being initiated.

Land and Freshwater Molluscs

MATT LAW and PAUL DAVIES

Bath Spa University, UK

Two classes of animals in the phylum Mollusca can be found in freshwater: bivalves and gastropods; gastropods may also be found on land (Figure 1). Bivalves have shells of two roughly equal-sized valves, hinged together. Many gastropods (“snails”) have external shells (often spiral) into which they can withdraw when inactive; some of these have a corneous or calcareous operculum attached to the foot which can seal the aperture of the shell for added protection against moisture loss. Other gastropods (“slugs”) lack a prominent outer shell, but some have a small internal shell (“slug-plate”).

The hard shells of molluscs consist of a number of layers. The outer layer, or periostracum, is composed of a protein called conchiolin. This often degrades quickly after burial (and in some cases may be abraded during life). The inner layers are made of calcium carbonate in complex arrangements of either of its crystalline forms, aragonite or calcite; sometimes both forms are present in the same shell. Because they are calcareous, shells preserve well where pH is high. This makes them complementary to pollen, which tends to preserve well where pH is low. Mollusc shells occupy a wide size range, from the large tropical Achatinidae, which can reach 30 cm in height, to *Angustopila dominikae* from China, around 0.86 mm in height. Most species are a few millimeters in their largest dimension, and so recovery during archaeological fieldwork requires sediment sampling (see SAMPLING IN ENVIRONMENTAL STUDIES), rarely supplemented by hand collection of shells.

Molluscs as proxies for past environments

Shells were noted in archaeological deposits in the nineteenth century, and in the first half of the twentieth century, and lists of the species represented at different sites began to be compiled. Knowledge of the preferred habitats of different species of land and freshwater molluscs in modern times began to be systematized in the middle of the twentieth century (for most of the world, this work is ongoing), which allowed researchers like Michael Kerney and Brian Sparks working in the United Kingdom to explore how changes in the species composition of shell assemblages through time reflected environmental change (Davies 2008, 1). The archaeological study of snails came of age with the publication in 1972 of the first book on the subject, *Land Snails in Archaeology* by John G. Evans. Subsequently, studies have been carried out globally, extrapolating from, and developing, the methods framed by Evans.

From the middle of the twentieth century, molluscan zonation schemes were created in southern Britain and some areas of continental Europe by Michael Kerney and others, the “zones” being stratigraphic associations of taxa which change in response to climatic variation. Another methodology for climatic reconstruction was developed in the late 1980s using Coleoptera, which has subsequently been applied to other biological groups including Mollusca (Moine et al. 2002). Known as the “Mutual Climatic Range” method, it relies on the climatic tolerances of particular species in the present day. The past climate of a location can be defined by the overlapping range of climatic conditions which would permit the taxa present to coexist, and is expressed in terms of the mean temperature of the warmest and coldest months (TMAX and TMIN).

Unlike some other invertebrates, in particular insects (see ARCHAEOENTOMOLOGY), molluscs tend not to be restricted to consuming a single

Figure 1 Anatomical terms for gastropod shells.

plant species, so they do not make good proxies for the presence of individual plant species. Some snail species, known as stenotopic species, have very narrow ecological tolerances across their whole range, however, in particular in environments that are subject to extremes (such as wet ground that dries out seasonally). These may be used as indicator species in paleoecology, although many stenotopic species are also very rare and so have limited utility. In general, however, the ecology of individual species depends on an often complex mix of variables, which each may vary in relative importance at different times or in different localities.

This problem has been overcome in paleoecology by the observation that modern, living snails occur in associations with particular relative abundances and that distinctive assemblages of snail recur in some paleoecological contexts. As these tend to be limited to a single taxonomic group in paleoecology, the term taxocene is used to describe these associations. Taxocenes are taxonomic segments of communities, and the members of a taxocene are likely to be closely analogous, having a similar size and similar life histories, and competing over both evolutionary and ecological time.

In the British Isles, molluscan studies have been especially productive where numerous sites of similar date have been explored within a region, for example the Wiltshire chalk or coastal machair of the Western Isles of Scotland. This has

allowed contrasting ecologies at a local scale to be detected and a detailed picture of human impacts on the environment to emerge (see Davies 2008 for a review).

A number of cautionary notes should be sounded when looking at molluscan assemblages, however. In many scenarios, rates of sedimentation are slow, meaning that shells found within the same depth range were not necessarily alive at the same time. At the very best, the shells recovered from a sample represent shells that became subfossils over the entire time it took the part of the deposit sampled to accumulate, and so are likely to represent a mix of the communities that existed during the period the deposit was laid down, rather than any particular community. Also, molluscan communities, although sensitive to change at a very local level, may respond to environmental change on a scale of decades rather than months or years, with the result that there is a theoretical lag in the site biostratigraphy between an environmental change taking place and it being detectable in the molluscan assemblage. In practice, slow rates of sedimentation may mask this lag. As Thomas (1985) has noted, despite theoretical problems, land snail analysis in archaeology has “worked” because the data make ecological sense.

Where variation in shell form exists within a single species, it can be quite revealing. For example, the European land snail *Discus rotundatus* has been shown to grow “taller” (that is, with a larger spire) in wetter conditions, and the coloring of the periostracum in some species can reflect the degree of vegetation cover, as these larger snail species may be subject to predation by birds. Goodfriend (1986) reviews a number of species worldwide that show such phenotypic plasticity which may have archaeological relevance—commonly, shells of many species (generally larger species, in particular Helicidae) may be larger with higher rainfall, larger on high-calcium soils, and smaller with higher population density.

Mollusc shells are also suitable for isotopic analyses. Oxygen isotope ratios may be used to reconstruct past temperatures, the $\delta^{18}\text{O}$ in the shells being primarily controlled by water ingested by the mollusc. However, in both terrestrial and especially freshwater shells a number of environmental variables may influence the

$\delta^{18}\text{O}$ of shell carbonate. In the case of molluscs collected for food, oxygen isotope analysis of the final growth increment (in gastropods, the edge of the shell lip; in bivalves, the outermost edge of the shell) may reveal the season of harvesting. $\delta^{13}\text{C}$ values in shells may be indicative of plant water relations in areas where C_3 plants dominate (Yanes et al. 2013).

Molluscs as food and medicine

Various larger species of land and freshwater mollusc are edible. These include larger Helicids such as *Helix pomatia*, *Helix lucorum*, *Cornu aspersum*, and *Theba pisana* in Europe, western Asia, and North Africa, and the giant land snails such as *Achatina achatina* and *Archachatina marginata* in Africa. Human terrestrial malacophagy has a long history: concentrations of cooked shells of *Iberus alonensis*, associated with structures thought to have been used for cooking, have been found at the Upper Paleolithic site of Cova de la Barriada, Spain (Fernández-López de Pablo et al. 2014). Various freshwater bivalves are also edible.

Some molluscs are vectors for endoparasites affecting humans; for example, the nematode *Angiostrongylus*, which can live within humans as an incidental host and cause meningitis, uses various edible molluscs as an intermediate host. A number of nonmarine mollusc species are used in traditional medicine; for example, the freshwater apple snail *Lanistes lybicus* is used in the treatment of conditions such as measles, ear complaints, and eye problems in Nigeria.

The dispersal of molluscs

Nonmarine molluscs may be dispersed through a number of means, including rafting across water on vegetation and being carried on the plumage of birds (or even internally, in some cases to emerge alive from the other end). The movement of people and goods is often implicated, however. Edible species may be deliberately transported live, as is probably the case with the arrival of *Helix pomatia* in Britain. Other species may be accidentally transported in cargo, for example the shells found within amphoras of terebinth resin on board the Bronze Age Uluburun shipwreck near

Turkey (Welter-Schultes 2008). Genetic analyses of living populations can be used to establish linkages between distant populations and, by proxy, identify routes of past human movement.

Molluscs and scientific dating

Mollusc shells are suitable for a number of isotopic dating techniques, including radiocarbon dating, especially when accelerator mass spectrometry (AMS) is applied, and particularly species with small shells. To be suitable for radiocarbon dating, the ^{14}C activity of mollusc shells must be in equilibrium with that of the atmosphere while the animal is alive, and the shell must be a closed system with respect to carbon after death. Pigati, Rech, and Nekola (2010) found that ca. 78 percent of shell aliquots from the smaller species of gastropod they studied living on carbonate terrain contained no old carbon, in contrast to reports of 20–30 percent dead carbon in some larger taxa, suggesting that larger taxa may yield unreliable dates. Other radiometric techniques applicable include uranium series dating (see URANIUM-SERIES). It can be applied beyond the range of radiocarbon dates, to materials from dates as old as 500 kya.

Some snail shells have proven to be particularly suitable for amino acid dating. Due to temperature-dependent variability in amino acid racemization, it can be hard to assign a definitive age to samples unless there is independent calibration available; however, the method can also be applied to establishing relative chronologies, a technique known as aminostratigraphy. It is best to use multiple samples, and to ensure that peptide-bound amino acids are also analyzed, in order to overcome problems of shells being chemically compromised (Penkman et al. 2007). The calcitic opercula of the freshwater gastropod *Bithynia* have been found to be especially suitable for amino acid dating as they have greater chemical stability than shell (Penkman et al. 2011).

Llamas and Alpacas

GABRIEL E. J. LÓPEZ
CONICET-UBA, Argentina

Introduction

South American camelids are artiodactyla mammals mainly distributed in the Andean area. The taxonomic classification of these animals places them in the Camelidae family, with two genera, *Lama* and *Vicugna*. Furthermore, four species are distinguished: Two are wild and the other two domesticated. The former comprise the vicuña (*Vicugna vicugna*) and the guanaco (*Lama guanicoe*), the latter the alpaca (*Vicugna pacos*) and the llama (*Lama glama*).

Modern vicuñas live in areas higher than 3,000 m asl in the Andes mountain range. The high plains in the Andes are known as *Puna* and constitute environments with different determinants for adaptation, such as hypoxia. These wild camelids feed on grasses spread in patches throughout the Puna and their social organization is based on territorial family groups and single groups. Vicuñas are the smallest animals in the Camelidae family, with an average weight of 45 kg.

Guanacos have a wide latitudinal and altitudinal distribution, from sea level (e.g., in Patagonia) to more than 4,000 m asl (on the Puna). They are herbivores, like the rest of camelids, and they also live in family and single groups. They are larger in size than vicuñas, with an average weight of 100 kg. However, their size varies depending on the latitude; for instance, larger animals are found in Patagonia than in northern Argentina and the Chilean Andes (Mengoni Goñalons and Yacobaccio 2006).

Llamas and alpacas are domesticated animals distributed throughout the Andean area. Alpacas prefer more humid environments, avoiding the arid Puna of the Central-South Andes (e.g., Argentinean Puna) and mainly inhabiting the more humid Puna in Peru and Bolivia. They weigh around 50/60 kg. Llamas, on the other

hand, are larger, weighing between 80 and 150 kg. They occupy different sectors of the Andean highlands and are adapted to the arid environment of the Puna, and are thus more widely distributed.

South American camelids were protagonists of a coevolutionary relationship with humans. Changes during the Holocene included intensification and domestication; this entry aims to analyze and briefly discuss these changes from an archaeological perspective.

Change processes and archaeological evidence

Human consumption of camelids has been recorded since around 11,000 years BP even in contexts where Pleistocene megafauna were present, such as the Pampa plains and Patagonia (e.g., Martin et al. 2015). Thus, camelids have been the most important protein source for human populations of different South American regions for more than 10,000 years.

Nevertheless, only in certain sectors of the Andean area did the coevolutionary process result in camelid domestication. Yacobaccio and Vilá (2013) present a model which involved different mechanisms of natural and artificial selection operating in this process. In a first phase—broadly the Early Holocene (ca. 11,000–8000 BP)—a generalized hunting would have developed. By the Middle Holocene (ca. 8000–3500 BP), increasing regional aridity had produced a greater segmentation of the landscape, creating patches of resources with subsequent concentration of humans and camelids in certain spaces. The reduction in mobility, increase in human group size, and growing demand for food would have promoted a process of intensification in camelid use. Similar processes of intensification are seen with other animals and plants in different parts of the world, linked to higher social complexity in human groups (see DOMESTICATION). Diverse indicators, fundamentally the increasing archaeological evidence coupled with radiocarbon

DOI: 10.1002/9781119188230.saseas0070

dates, would indicate population growth towards the end of the Middle Holocene in the Puna (ca. 5000 BP) (Muscio and López 2016). This chronology coincides with evidence of camelid domestication at a macroregional scale. Following Jacobaccio and Vilá's model (2013), the stage previous to domestication, namely the development of protective herding mechanisms, is indicated by human groups facilitating access to grasses for camelids and providing them with protection against predators. Finally, the animals were separated and held in captivity, leading to domestication.

Broadly speaking, intensification may be defined as the search for a higher productivity per space unit or resource. Domestication implies a process where animal and/or plant populations adapt to humans and the environment through genetic change over many generations along with developmental events which are environmentally induced (Jacobaccio and Vilá 2013). Research carried out in the last few decades has been able to establish the ancestors of domesticated species. In the case of alpacas, the current view considers the vicuña as their wild ancestor (Kadwell et al. 2001). Domestication of alpacas from vicuñas would have developed in the Central Andes between 7000 and 6000 BP (Wheeler 1999), although some authors propose later dates (5000–4000 BP) (Marshall et al. 2014). On the other hand, llamas derive from the domestication of guanacos. Archaeological evidence of this process suggests that this occurred between ca. 5000 and 3500 BP, though earlier records are also known (Mengoni Goñalons and Jacobaccio 2006). DNA studies were fundamental to defining the origin of domesticated camelids (see ZOOARCHAEOLOGY AND ANCIENT DNA). However, recent studies show that interbreeding occurred and that this process was more complex (Marshall et al. 2014).

Figure 1 presents the location of some of the sites with evidence of changes related to camelid domestication. In the Central Andes, specifically in the Puna de Junín, Peru, the Telarmachay site recorded changes leading to the domestication of alpacas in ca. 6000 BP (Wheeler 1999). Other sites in the Puna de Junín such as Pachamachay and Panaulauca yielded evidence of domesticated camelids ca. 4000 BP. To the south of Peru, the Asana site also indicated changes toward camelid domestication in ca. 3600 BP (Aldenderfer

1998). Furthermore, in northern Chile and the Argentinean Puna, several sites reported evidence of domestication and/or presence of domesticated camelids by ca. 5000 BP. In the Atacama Puna, Chile, such changes were detected in the archaeofaunal record at Tulán 52 and Puripica 1 (Cartajena 2013). Additionally, in the highlands north of Argentina, sites such as Inca Cueva 7 (ICc7), Alero Unquillar, Huachichocana III (Ch III), Abrigo Pozo Cavado (APC), Alero Cuevas, Quebrada Seca 3, and Peñas Chicas 1.5 also produced evidence of changes leading to camelid domestication, particularly in llamas (López and Restifo 2012; Jacobaccio and Vilá 2013).

Several analyses were used to study these processes, such as dentition, osteometry, age at death profiles, characterization of fibers, and contextual analysis. As aforementioned, DNA analysis was fundamental to the progress of these studies.

Regarding dentition, variability in incisors was used to define the presence of alpacas in early contexts in the Central Andes (Wheeler 1999). Furthermore, osteometry was applied in the Andean area to distinguish the different species of camelids by measuring bone size. These analyses were crucial to differentiate domesticated from wild camelids. Additionally, age profiles were similarly considered as evidence for domestication (Wheeler 1999). An increase in subadult camelids, particularly newborns, is seen at several sites in the Central Andes, particularly Telarmachay (Wheeler 1999). These changes are interpreted as the result of diseases caused by the animals being kept in confined conditions during the process of domestication. In other contexts of the Central-South Andes, the high representation of subadults could be related to a process of intensification of hunting to satisfy the higher demand for food (López and Restifo 2012), although it is possible that both processes (intensification and domestication) happened in conjunction (López and Restifo 2012). Other evidence for distinguishing among camelid species is the variability in their fiber (see FIBERS). The record at Quebrada Seca 3, in the Argentinian Puna, indicates the presence of camelid fiber similar to llama's at early times (ca. 9000 BP) (Reigadas 2008). Lastly, contextual indications such as the presence of dung layers or corrals are relevant for the study of domestication. At Inca Cueva 7 (ca. 4000 BP) and Asana (ca. 3600

Figure 1 Archaeological sites with evidence of changes toward camelid domestication in the Andes.

BP) there is evidence of camelids in captivity (Aldenderfer 1998; Yacobaccio and Vilá 2013).

In recent decades, research on camelids has diversified. Techniques and approaches include taphonomic analysis (see TAPHONOMY), consideration of the age and sex structure of camelids, and research on stable isotopes (see ZOOARCHAEOLOGY AND STABLE ISOTOPES). The many lines of evidence can be used to explore changes in human society. This entry has focused on the processes of camelid intensification and domestication in the Andean area, but other questions can be explored.

Camelids have provided the main animal food resource for the different populations in South America for 10,000 years. Hence, research on the relationship between camelids and humans will certainly open new areas of enquiry in the future.

Maize

BRUCE BENZ

Texas Wesleyan University, USA

As early as 1945, Isabel Kelly's excavations along the Tuxcacuesco reach of the Rio Armeria in southwestern Jalisco, Mexico produced significant evidence of agricultural dependence on maize, agave, and other forest products. Edgar Anderson (in Kelly 1949) described the first archaeological evidence—a carbonized cob—as a narrow rachis with ten rows of grain. The suggested date, by ceramic association, was Pre-Classic West Mexico (ca. 350 BCE to 300 CE). In the 70 years since Kelly's findings when morphological description of macroscopic remains from relatively dated contexts was possible, we now routinely date macrobotanical evidence directly. Indirect dating of microscopic phytoliths from stratigraphic profiles or from grinding stones is still the norm. Significant improvements now permit modeling the rates of genetic change in maize since teosinte's domestication and the impact of climate change on Mexican annual teosintes and land races (Hufford et al. 2012a; 2012b; Swarts et al. 2017).

Archaeological evidence of maize agriculture includes: pollen, phytoliths, starch grains, corn cobs, and macroscopic remains of maize and its wild relative teosinte; isotopic signatures in the animals that consume maize, including humans; ancient DNA; ceramic representations; corn preparation tools and residues they adhere to; and linguistic and pictorial representations on many graphic media (Staller, Tykot, and Benz 2006). All these materials add to our knowledge of how and when maize was utilized and the role it has played in ancient societies. All materials come with certain caveats and all have their proponents and critics. This entry briefly describes the archaeological evidence for the early use and domestication of maize, with particular reference to recent research. It focuses on dating evidence, macrobotanical material, pollen, phytoliths, and starch grains (Figure 1).

Types of archaeological material

The types of evidence used by archaeologists to make inferences about the origin and evolution of maize have, until recently, been limited to macrobotanical material (see PALEOETHNOBOTANY), pollen (see PALYNOLOGY), phytoliths (see PHYTOLITH ANALYSIS), and starch grains (see STARCH GRANULE ANALYSIS). However, ancient DNA analysis (see PALEOETHNOBOTANY AND ANCIENT DNA ANALYSIS) is now becoming common in the archaeological literature (Swarts et al. 2017).

Pollen grains have been long associated with maize research. Since the discovery of pollen grains at Guila Naquitz, Oaxaca, Mexico by Schoenwetter (1974), numerous studies on sediment cores from archaeological contexts, estuaries, lakes, and coastal swamps have found evidence for maize and teosinte (Blake 2015; Blake et al. 2017; Staller et al. 2006). However, because maize has pollen grains that cannot be reliably distinguished from teosinte or *Trip-sacum*, care should be taken when interpreting the evidence (Holst, Moreno, and Piperno 2007).

In the Gulf of Mexico, the San Andres locality in Tabasco yielded a long sequence—7100–2486 cal. BP (median years calibrated radiocarbon date before present; all subsequent reports follow this format)—containing *Zea* pollen, showing an increase in size up through the sequence which was interpreted as reflecting the evolutionary sequence from teosinte to maize. Pollen from Zohapilco, near Chalco, Mexico occurred at 4795 cal. BP and was dated by association with two teosinte fruit cases. In Belize, the site of Cob Swamp in Corozol likewise produced indirect dates (stratigraphically associated) dating from 5341 to 2876 cal. BP. In Guatemala, the Sipacate site in Escuintla produced *Zea* pollen from 5489 to 3090 cal. BP. *Zea* pollen occurred twice at Lago Puerto Arturo, Peten, Guatemala, at 5172 and 3224 cal. BP, while at Rio Naranjo, San Marcos, Guatemala, *Zea* pollen was found at depths dated 4611 and 3825 cal. BP. In Central America, *Zea* pollen was recorded at around 5512–4988

cal. BP at Laguna Martinez, Guanacaste, Costa Rica. A very similar age date (5464 cal. BP) on associated pollen came from Lake Yojoa, near Cortes, Honduras. In Colombia, the date 5357 cal. BP associated with *Zea* pollen came from El Dorado, Yotoco, Valle del Cauca. Pollen of *Zea* was also encountered in Araracuara, Solano, Caqueta, Colombia (5302 cal. BP), and much later at Araracuara 3 (around 1017 cal. BP). Pollen grains identified as *Zea* occurred at three separate depths of 5156, 3488, and 2460 cal. BP

in Lake Ayauchi, Morona Santiago, and Ecuador, respectively. *Zea* pollen was found in the cultural deposits of Los Gavilanes, Huarmey, Ancash, Peru dated to around 4591 and 4044 cal. BP, and at Caballete, north of Lima, Peru at 4449–3982 cal. BP and nearby Porvenir around 4732 cal. BP. To the north, pollen occurred in lake sediments only 663 and 667 cal. BP years ago in Laguna Castilla, Azua, Dominican Republic. In New Mexico, *Zea* pollen was recorded in a pack rat midden (CC3) in San Juan, and in New Mexico twice, at 4383

and 2767 cal. BP. It was also found as far north as the Crawford Lake site, Campbellville, Ontario at around 672 and 663 cal. BP (Blake et al. 2017).

Early occurrences of maize phytoliths were documented in Monte Oscuro, Panama, dating from 8311 and 6749 cal. BP. The Aguadulce rock shelter in Cocle, Panama produced phytoliths dating from 7746 to 7102 cal. BP. Chirique, Panama produced phytoliths at 7141 cal. BP and again at 6732 cal. BP. Cueva de Los Ladrones and Aguadulce yielded phytoliths on tools and in midden samples at around 7701 and 7101 cal. BP, respectively. To the north and west, coastal swamp sediments from SOC 05-2, Pijijiapan, Chiapas, Mexico were dated to around 6589 cal. BP. San Andres, Tabasco, Mexico also produced a few phytoliths, these occurring in association with the earliest pollen at 7101 cal. BP. Samples from the Las Vegas site, Santa Elena, Ecuador produced phytoliths indirectly dated at 7915 cal. BP. Phytoliths appear at Huaricanga and Porvenir north of Lima at 4873 and 4732 cal. BP, and in Waynuna, Condesuyas, Arequipa, Peru from 4029 until 3721 cal. BP. Phytoliths are recorded much later in New York: at Fortin, South Kortright dating to 1945 cal. BP; and then 1409 cal. BP and 1941; at Vinette, Oswego dating to 1890 cal. BP; and from 1358 to 1330 cal. BP at the Kip Island site, Cayagu. Phytoliths also occur slightly later—1163 and 1138 cal. BP at the Hunter's Home Site, Savannah, New York (Blake et al. 2017).

Starch grains of maize have been recovered on tools and ceramic vessels. These grains have been identified from numerous sites throughout the Americas (Blake 2015; Blake et al. 2017; Staller et al. 2006). Most are dated indirectly. The earliest come from tools in contexts dated 8750 cal. BP at Xihuatoxtla, Huizuc de los Figueroa, Guerrero, Mexico. Starch grains reoccur at Xihuatoxtla in association with dates of 5475, 2891, and 1126 cal. BP. Panamanian research produced starch grains in association with tools at Cueva de los Ladrones and Aguadulce at around 7707 and 7702 cal. BP, respectively. Starch grains were found on a single Archaic (6655 cal. BC) stone tool at Caye Coco, Corozal, Belize. The Valdivia culture site of Loma Alta, Guyas, Ecuador produced numerous occurrences of starch grains dating from 5647 to 4982 cal. BP, though maize macroremains do not appear until 2,500 years later. Santa Ana-La Florida in the Ecuadorian highlands yielded

dated samples and associated starch grains at 4979 cal. BP. Sites on the Peruvian coast have produced artifacts with starch grains that are slightly later in date to the Ecuadorian coastal sites; Huaricanga near Lima, Peru produced dated contexts with starch grain-laden tools at 5159 and 4873 cal. BP (Blake et al. 2017).

Maize cob fragments, cupules, and kernels are much more numerous in the archaeological record than any other types of evidence for this species; most occur in Mexico. The earliest macroscopic corn cobs appear at 6229–6222 cal. BP at Guila Naquitz, on the northern margin of the Central Valley of Oaxaca, Mexico. Their morphological characteristics indicate domestication (Benz 2001), though they are not typical of the cobs found today. Around 800 years later, numerous cobs occur within rock shelters in the Tehaucan Valley, Puebla, beginning at San Marcos (5434–4689 cal. BP), Coxcatlan (4545–4098 cal. BP), and El Riego (4272 cal. BP). Maize persists at these localities until the time of Spanish contact. Maize cobs and teosinte occur coincidentally in the strata of El Romero's cave in southern Tamaulipas, Mexico, at around 4630–4380 cal. BP. Not long after, maize appears in New Mexico at the appropriately named Old Corn site, with cobs, cob fragments, and kernels dating between 4207 and 3932 cal. BP. Maize from McEuen Cave overlooking the Gila River in eastern Arizona (4030 cal. BP) and from Three Fir shelter in Navaho, Arizona (3940 cal. BP) in northeast Arizona is of slightly more recent origin, as are numerous maize kernels at sites in the Santa Cruz river basin northwest of Tucson, Arizona at Clear Water (4061–4030 cal. BP) and Las Capas (4003 cal. BP). Other sites in the Tucson Basin represent a persistence of maize agriculture that begins at Los Pozos at around 3720–3246 cal. BP and reappears from 2345 until 2141 cal. BP. The Los Pozos hiatus is bridged at El Milagro (3090–2878 cal. BP), Costello-King (2884–2746 cal. BP), Solar Well (2965–2235 cal. BP), and Cortaro Fan (2897–2858 cal. BP) (Blake et al. 2017).

Meanwhile, far to the south and east of Guila Naquitz, the site yielding the most ancient maize to date, the rock shelter known as El Gigante in La Paz, Honduras, yielded cobs as old as those from the Old Corn site in New Mexico (4373–3997 cal.

BP). Maize persists through the cultural strata at El Gigante up to the time of Spanish contact.

Even farther south, the site of Paredones, Ascope, La Libertad, Peru produced a wealth of maize, some of it securely dated at around 4861 cal. BP. Other specimens have aberrant C^{13} values, suggesting contamination. The nearby site of Huaca Prieta also contained maize cobs that dated to 4074 cal. BP. Maize is common in sites along the Pacific coast of Peru and Chile, most of which are more recent than the cobs from the Ramaditas site in Provincia Iquique, Primera Región de Tarapacá, Chile (2154 cal. BC) (Blake et al. 2017).

Grains and cob fragments dated to the second millennium BCE (2000 cal. BP) occur in the United States: including Georgia, at the Rush site, near Floyd (1444 cal. BCE); Tennessee, at the Ice House Bottom site near Jamestown (1698 cal. BCE); Ohio, the Edwin Harness Site, near Groveport (1647–1637 cal. BCE); and Illinois, the Crane site near Greene (1402 cal. BCE). Two dates on maize cupules from the Grand Banks site near Cayuga, Ontario are of similar antiquity (1468–1421 cal. BCE).

When was maize domesticated?

According to recent genetic research, maize evolved from its ancestor teosinte (*Zea mays* ssp. *parviglumis*), and experienced some introgression from highland teosinte (*Zea mays* ssp. *mexicana*) (Hufford et al. 2012a; van Heerwaarden et al. 2011) prior to dispersal in its current form. The antiquity of this process is hypothesized by some to have occurred slightly less than 9,000 years ago, and by others at around 6,300 years ago. The tropical lowlands of West Mexico appear to have been the locus of early maize evolution. The timing of the domestication process is clouded by a plethora of pollen, phytolith, and starch grain finds, most of which are indirectly dated and uncorroborated by associated macrobotanical evidence—with macrobotanical evidence only occurring 2,500 years later. On the other hand, the macrobotanical evidence clearly documents the domestication syndrome of crop plants' phenotypic evolution, followed by gradual evolutionary increase in grain number and size. This evolutionary process has not been documented

in the tropical lowlands of western Mexico, where genetic evidence suggests it should occur, but at mid-elevation localities—Guila Naquitz, Tehuacan—distant from the site of presumed domestication. The domestication of maize is well documented from a genetic point of view, but less well archaeologically. The confluence of these two areas of study is providing new insights (Swarts et al. 2017). Stay tuned.

Marine Molluscs

KENNETH D. THOMAS

University College London, UK

Shells of marine molluscs from archaeological contexts can inform about the environmental, chronological, subsistence, behavioral, and social contexts of people in the past. Studies of marine molluscs in archaeology have a long history, but in recent years these have proliferated greatly, alongside increasingly diverse analytical methods and research applications.

Molluscs occur in most environments occupied or exploited by humans. Although particularly diverse in marine environments, they have adapted to nonmarine habitats (see LAND AND FRESHWATER MOLLUSCS). Bivalves (clams) and gastropods (sea snails) are the groups most frequently found in archaeological deposits; other marine groups (chitons, scaphopods, and cephalopods) occur less frequently. The ecology of species is also highly variable, making them good indicators of past environments.

In many coastal regions of the world, huge numbers of shells, principally species with high food value, form the main component of shell middens, some occurring as large topographical features. Most of the marine molluscs found in archaeological deposits inhabited the inter-tidal zone of shores where they could be collected at low tides, although shallow-water subtidal species can be obtained by diving. The empty shells of deeper-water species can be cast up onto shores by storms or strong wave action and be collected by people. Marine shells also occur at inland archaeological sites, such as within inhumations, with small perforated shells of ornamental or symbolic significance.

The recovery, identification, and quantification of assemblages of marine shells from archaeological sites is covered by Claassen (1998) and Harris, Weisler, and Faulkner (2015). Once the species and their numerical abundance are established, interpretations can be made of past

human choices of the species gathered and the types of shores exploited. A preponderance of large edible species suggests collection for consumption, while smaller shells might have been collected as ornaments. While useful information can be gained from the composition of the assemblage, various analytical procedures can reveal much more.

Most marine molluscs grow their calcareous shells throughout life, growth being added incrementally at the shell edge in bivalves or the aperture in gastropods. These growth increments constitute a time-series, or sclerochronology (Greek: *scleros*, hard; *chronos*, time) which records environmental conditions experienced by the animal over its life; for more about sclerochronology see Andrus (2011). Bivalves have provided the highest levels of resolution of shell growth intervals and been most studied, although gastropods are increasingly being investigated. The integration of sclerochronology with analyses of stable isotopes of oxygen ($\delta^{18}\text{O}$) and carbon ($\delta^{13}\text{C}$) in shell carbonates (see Leng and Lewis 2016) is a powerful tool for investigating past climate, environmental change, and past human behavior.

Marine shells are suitable for radiocarbon dating by accelerator mass spectrometry, provided caution is exercised in the selection of shells, and in calibrating and interpreting the dates. Shells selected for dating should represent human activity close to the time of the death of the mollusc, such as food discard. Dates are generated from the calcium carbonate in shells and mineral diagenesis can lead to either older or younger carbon being incorporated into the shell crystals, distorting the resulting date. Macroscopic and microscopic indicators can help identify recrystallized marine shells. The marine reservoir effect, where old carbon becomes incorporated into the growing shell, can produce dates that are too old. Reservoir age variations (ΔR), calculated from radiocarbon determinations on marine animals (often mollusc shells) of known chronological age, are widely available for local corrections and calibrations. Knowing ΔR for a coastal region or locality is essential for the calibration of radiocarbon determinations using a marine calibration

curve. Filter-feeding (predominantly bivalve) molluscs have been preferred for dating purposes because their principal carbon sources are phytoplankton and dissolved inorganic carbon in the seawater. Gastropod shells have been less favored because they can ingest deposits with either enriched or depleted radiocarbon as they graze, although perfectly acceptable radiocarbon dates have been obtained from selected gastropod species. Recent improvements in laboratory techniques, such as the recovery of intracrystalline amino acids, offer hope for reliable amino acid racemization dating of marine shells. For further discussion of dating of mollusc shells and references to key literature, see Thomas (2015a).

Large accumulations of shells of edible molluscs could indicate they were a significant human food resource in the past, although this significance is reduced if caloric contribution is taken into account. There are, however, more facets to diet than calories alone and marine molluscs provide important nutrients such as proteins and trace elements. They are available and easily procured at all times of year, including times when alternative food sources might be scarce. The relative importance of marine molluscs and other marine food in past human diets is increasingly being investigated through the stable isotopes of carbon, $\delta^{13}\text{C}$, and nitrogen, $\delta^{15}\text{N}$ (see DIET AND CARBON ISOTOPES and DIET AND NITROGEN ISOTOPES) in collagen extracted from human bones. Such studies have shown, for example, that while marine foods were significant in Late Mesolithic (6th millennium BCE) hunter-gatherer diets along the Atlantic coast of Europe, in the Mediterranean they played a minor role in hunter-gatherer diets. Most marine molluscs are either primary consumers or detritivores and have $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ values close to those of marine algae; therefore their consumption by humans would give only a weak “marine food” isotope signal compared with higher-trophic-level marine animals, such as fish (see FISH).

Oxygen isotope data ($\delta^{18}\text{O}$) on season of harvest of marine molluscs can be useful for studies of past human subsistence. A mollusc dies when harvested by a forager, and the temperature-related $\delta^{18}\text{O}$ signature in the final growth increments of its shell indicates when in the year this happened. To determine seasonality of collection, the $\delta^{18}\text{O}$ values in shells must

record full annual temperatures; that is, shells must grow all year round, and often it is necessary for researchers to undertake field-based studies to confirm this. Seasonal patterns of marine mollusc exploitation at a site, or between sites in a region, are usually established using a selected species as a proxy for the seasonality of all mollusc-gathering activities, but ideally more species should be used. The number of samples from final growth increments required to establish season of death of each shell also needs validating for each particular species, especially fast-growing species where accuracy is low if only one or two samples from the terminal growth stages are analyzed.

The potential for human foragers to impact their marine mollusc resource base is of considerable interest and debate. A decrease in the size of shells over time in archaeological deposits can be attributed to predation pressure from human foragers, provided other environmental causes can be discounted. Some recent studies have shown increases in the size of certain species of exploited molluscs, and although the reasons invoked for this are varied, they demonstrate that different outcomes can arise in particular multifactorial ecological and cultural contexts. Even if human foragers periodically depleted a mollusc species, there is no reason to suppose they caused even local extinction. Past human foragers must have been ecologically knowledgeable, because their livelihoods depended on it, and they would have devised strategies to cope with resource depletion, such as switching to alternative resources, or foraging at localities where resources were not depleted. Such strategies serve as a means of resource management. Perhaps the most sophisticated way to manage shellfish resources is by some form of “cultivation.” Mussels (*Mytilus californianus*) from a rock shelter in coastal northern California appear to have been harvested intensively at intervals of around 24 months, allowing a “fallow” period for the populations to recover. More sophisticated still are Late Holocene “clam gardens,” intertidal stone-walled terraces in British Columbia, Canada, constructed to create optimal growing conditions for high-density “cultivation” of clams. For further discussion of seasonality and of marine molluscs as human resources, with references to key literature, see Thomas (2015b).

Mollusc shells have long been used for decorative and utilitarian purposes. They show great diversity of size, shape, robustness, and so on, which affect the manufacture, use, and performance of shell tools, and the technological choices shell-workers have to make. The degrees of modification of shells to produce artifacts and the levels of technology required are highly variable, depending upon skill, the equipment available, the physical properties of the shells being exploited, and the types of artifacts required. Sometimes virtually no modification is needed; for example, scaphopod molluscs have natural holes at each end of their tubular shells, making them “natural” beads. Unmodified mollusc shells can be used as tools and, unless modified by wear during use, this use might be undetectable; see Szabó (2013) for the identification of shell use. Investigations of the use of shell tools are patchily represented in the literature. A use-wear analysis of Upper Paleolithic shell tools from a cave in northern Spain showed they had been used for a range of procedures, including the processing of red pigments (used for cave wall painting) and the treatment of animal hides. Studies of residues resulted in the identification of starch granules (see STARCH GRANULE ANALYSIS) on shell tools in Polynesia, providing evidence of processing of local crop plants and of the specific uses of the shell tools themselves. Marine mollusc shells have also been used in a range of other ways, such as crushed in mortar, and other products have been extracted from molluscs, most notably dyes (see DYES) from various species of gastropods.

The linkages between personal ornaments and the origins of modern human cognitive behavioral traits such as symbolism have been highlighted in recent years. Some of the earliest known examples are of the bivalve *Glycymeris* associated with pieces of red ochre in Middle Paleolithic contexts in Qafzeh Cave, Israel, 92,000 years ago. Very early shell beads with clear evidence of deliberate perforation occur in Middle Stone Age deposits at Blombos Cave, South Africa, from 76,000 years ago. Neanderthals may have used shells as pigment containers, ornaments, and tools such as scrapers, even before modern humans had evolved.

Shells from sites outside the natural geographic distribution of mollusc species provide evidence for provenience and exchange. Long-range connections across at least 1,000 km have been inferred from artificially perforated marine shells of Mediterranean origin from an Upper Paleolithic site in Germany. Analytical data are of increasing value for determining provenience. Artifacts from the marine bivalve *Spondylus gaederopus* are widely distributed across Neolithic Europe, and oxygen ($\delta^{18}\text{O}$) and strontium ($^{87}\text{Sr}/^{86}\text{Sr}$) isotope analyses reveal the Aegean or Adriatic, rather than Black Sea, origin of these shells.

Scientific studies of marine molluscs allow archaeologists to investigate many aspects of past human behavior. Recent innovations have extended the range of questions that can be investigated, with increased output of high-quality research. This trend looks set to continue, carried forward by the many young scholars entering this exciting field.

Oils and Fibers

OTTO BRINKKEMPER

Cultural Heritage Agency of the Netherlands,
Netherlands

Remains of oil crops are regularly encountered during paleoethnobotanical (archaeobotanical) research (see PALEOETHNOBOTANY), those of fiber crops much less so. Such finds provide the scientific basis for this entry, which focuses on the use of these crops in Europe.

Both types of plant remains are relatively seldom found charred, which is the most common state of preservation encountered, and particularly relevant for the recovery of cereal remains. This strongly influences the observed distribution pattern of oil crop finds, and even more so of fiber plants. Waterlogged preservation is usually necessary for the recovery of fiber crops (apart from desiccated preservation which is restricted to arid regions and salt caves (see FORMATION PROCESSES)).

The use of oil-rich seeds considerably predates the introduction of agricultural practices in western Europe. Oil-rich hazelnuts were commonly gathered in hunter-gatherer societies following hazel's post-glacial spread into the region during the Boreal period (ca. 8000 BCE). With the introduction of agricultural knowledge in this area during the Early Neolithic Linearbandkeramik (LBK) culture (ca. 5300 BCE) (see DOMESTICATION), two cultivated crop plants with oil-rich seeds arrived on the scene: linseed/flax (*Linum usitatissimum*) and small-seeded opium poppy (*Papaver somniferum* var. *setigerum*).

Flax can be cultivated both for its oil-rich seeds and for its fibers. Both uses can result in finds of seed remains, but occasionally more information on the former use of this crop can be gained. The utilization of linseed oil is difficult to demonstrate by archaeobotanical means. The fact that in waterlogged material sometimes only the rims of the seeds are found might relate to the pressing of the seeds to extract oil, but digestion

(by people or livestock) has comparable effects. Herbig and Maier (2011) demonstrated significant differences in flax/linseed seed size which they linked to the use of the plants. Large-seeded specimens point to the use of the oil-rich seeds and small-seeded ones to the use of fibers (Figure 1).

Remarkably, whereas linseed belongs to the eight Neolithic founder crops domesticated within the fertile crescent in the Near East, this is not the case for opium poppy. Bakels (2009, 30) inferred a western Mediterranean origin for this crop and proposed that a "French connection" was involved in the spread of opium poppy to the Dutch and German LBK farmers.

Although the dataset is still patchy, flax seems to have maintained its status as a crop plant until the present day. Opium poppy, in contrast, vanished from the crop record during the Bronze Age, only erratically occurred during the Iron Age (800–12 BCE) and returned as the larger seeded var. *somniferum* during the Roman period. This again points to a Mediterranean connection, the vector being the Roman garrisons that were established over large parts of Europe.

In the Bronze Age, the range of oil crops grown was not enlarged, but during the Iron Age, two new species with oil-rich seeds were taken into cultivation, both belonging to the crucifer family. Most widespread was gold-of-pleasure (*Camelina sativa*), with turnip (*Brassica rapa*) of more local importance. The larger range of oil crops grown during the Iron Age coincides with the increase in other types of crops. This is most likely related to the much wider variety of soil types inhabited and used for cultivation, including wet environments like salt marshes and peats. In fact, gold-of-pleasure was the most common crop at the Dutch Early Iron Age site of Assendelft situated on a raised bog (Therkorn et al. 1984), being one of the very few crops suited for this extreme type of environment—just like the faunal main component at this site, sheep. In the estuary of the River Meuse, during this same period a specialization in oil crop cultivation seems to have taken place, with linseed and

Figure 1 Dimensions (width and length) of flax seeds in lakeshore settlements at Lake Constance and in Upper Swabia. Two distinctive clusters show the large-seeded “Pfyn-type” flax in the early phase of the Late Neolithic and the small-seeded “Horgen-type” from the middle and latest phase of the Late Neolithic.

Source: Republished with permission from Springer, Herbig & Maier 2011.

gold-of-pleasure occurring on Spijkenisse 17–35 and turnip on Spijkenisse 17–30 (Brinkkemper 1993, 138).

In (proto-)historic times, the range of oil crops grown is supplemented by hemp (*Cannabis sativa*), which has a dual purpose just like flax, as it can be grown for both fiber and its oil-rich seeds. In several countries, the Roman occupation seems to have led to the spread of this crop into new areas. The common occurrence of hemp seeds in medieval cesspits clearly evidences seed consumption. Black mustard (*Brassica nigra*) became common during the Roman period and even more so in medieval cesspits. This crop weed might have been purposefully collected, or even cultivated, for its tasty seeds.

Major plant oils from other parts of the world include coconut, cottonseed, olive (see OLIVES AND OLIVE OIL), palm, peanut, safflower, sesame, soybean, and sunflower. In addition, a long list of plants were used to produce oil, but on a much smaller scale, and usually with greater difficulty.

Remains of all of the main oil plants have been found in archaeological contexts, and the use of their plant oils is likely.

Just as with oil-rich seeds, fibers were being used by humans from an early date. The use of bast fibers from the phloem of certain trees, especially lime (*Tilia* sp.) and elm (*Ulmus* sp.), in the production of ropes and nets was already known to Mesolithic hunter-gatherers. In several Neolithic contexts (ca. 5500–2000 BCE) throughout Europe, flax fibers (linen) have been recorded, clearly evidencing their use in textile production. The Swiss lake-side settlements with their waterlogged preservation conditions produced a wealth of plant (and animal!) fiber products. In an overview of Neolithic and Bronze Age fibers from these sites, Rast-Eicher and Dietrich (2015) recorded oak, lime, and willow bast, in addition to the fibers from cultivated flax. For the production of linen from flax stems, retting is required. Retting is a process involving microorganisms and moisture on plants to rot

away much of the cellular tissues surrounding plant fiber bundles, to facilitate separation of the fiber from the stem. Retting can be done either in water or by means of dew on land.

This odorous activity leaves recognizable traces, as is demonstrated by the combination of pollen and macro-remains in medieval pits in the Netherlands (Pals and Van Dierendonck 1988). Vice versa, the demonstration of flax retting implies the production of linen. In China, where linseed has been used for over 2,000 years, the use of flax for fiber appears to have started only in the last century (Liu et al. 2011).

Hemp probably originates from eastern Asia, where it was used for rope, clothing, sails, and bowstrings by 6200 BCE (Warf 2014). Whereas flax fibers have occasionally been recorded in archaeological sites, finds of hemp fiber are very rare. During pre- and proto-historic times, other noncultivated plants are likely to have been used for fiber production. Nettle seeds (*Urtica* sp.) in particular, are almost ubiquitous in the archaeological record and occasional finds of nettle fiber are known. Desiccated remains of baskets, regularly found in Egypt, demonstrate that leaves and leave-sheets of palms and leaves of grasses were used for a variety of products, from donkey saddles to containers and brooms, with only minimal processing required (Wendrich 1999).

Other fiber crops include cotton, jute, ramie, sisal, and coconut, with only a few plant families involved—Malvaceae (cotton, jute), Agavaceae (sisal), and Urticaceae (ramie). It is only in relatively recent times that use of these tropical fibers became a feature of the European economy.

Olives and Olive Oil

WENDY SMITH

University of Birmingham, UK

Olive (*Olea europaea* L.) is an oil-rich fruit, native to the Mediterranean/Near East, which usually is cured by fermentation in solution with brine, lye, or salt to remove bitter phenols before eating. Pressed olive fruits produce oil which can be used for cooking, lighting, or as a base to medicinal/hygienic products such as ointments, perfumes, and soaps. Cultivated olive is one of the earliest domesticated fruits, most likely brought into cultivation shortly after cereal cultivation developed in the Fertile Crescent. Along with grapes (see GRAPES AND VITICULTURE) and wheat (see WHEAT), olives are a member of the Mediterranean triad (the suite of plants underpinning ancient agriculture in the region).

Despite substantial historical and archaeological information, there are fundamental gaps in our knowledge of cultivated olive and its wild progenitor(s). Debate about when and where olive oil processing first occurred and, indeed, if “table olives” were consumed prior to the Hellenistic period (e.g., comment in Kaniewski et al. 2012) is due, in part, to the lack of comprehensive data (by both regions and periods). Oleaculture suffers, especially, from being well documented in historic periods and, like cereals or grapes, is so ubiquitous to Mediterranean/Near Eastern agriculture as to be taken for granted. English-language reviews of oleaculture in Greece (Foxhall 2007) and North Africa (Mattingly 1996) provide a useful introduction to the socioeconomic value of olives to ancient Mediterranean societies, but we should remember that many of the cultures of the Mediterranean (e.g., the Phoenicians, early Minoans, Etruscans) are not as well documented.

There are approximately 40 evergreen tree/shrub taxa within the genus *Olea*, which subdivide into three subgenera: *Olea*, *Paniculatae*,

and *Tetrapilus*. Molecular dating from modern material (i.e., genetic generational sequences based on the mutation rate of nucleotide sequences of DNA—in this case plastid DNA and ITS-1 sequences—suggests that the genus *Olea* has an evolutionary history spanning the Tertiary (ca. 66–2.5 Ma) and genetic divisions between subgenera or sections coincide with major climatic events. In particular, diagnostic peltate plates surrounding (sometimes completely obscuring) leaf stomata are unique to *Olea* section *Olea* and may represent genetic adaption to desertification; this water-saving adaptation marks the separation of section *Olea* from section *Ligustroides* within the subgenus *Olea* at ca. 17.7 Ma (coinciding with the Mid-Miocene climatic optimum—Besnard et al. 2009).

The wild form of olive, known as oleaster (*Olea europaea* L. var. *sylvestris*), has existed since the Pleistocene (ca. 2.5 Ma to ca. 11,700 BP) and its fruit pits are indistinguishable from cultivated olive (*Olea europaea* L. var. *europaea*). Oleasters tend to be shrub-like, while cultivated or feral olives occur as trees. There are some potential differences between cultivated olive wood and wild oleaster wood (e.g., Terral and Arnold-Simard 1996); nevertheless, it is still considered problematic to distinguish wild from cultivated olive wood. Fossils and studies of olive charcoal/pollen from Middle–Upper Paleolithic sites in the Mediterranean suggest that oleaster survived the last glaciation in refugia. It is believed that the olive tree was brought into cultivation quite early in the Holocene from either the wild oleaster form or the true *Olea europaea* L. var. *europaea* form, but the precise timing and location(s) of this event are not yet known. By the third millennium BCE, olive trees were cultivated throughout the Mediterranean and Near East.

Olive pits are easily identified using conventional paleoethnobotanical methods (see PALEOETHNOBOTANY) relying on low-power microscopy. Archaeologically, olives are encountered most frequently as charred plant remains

(pits or charred wood), but also occur through other modes of preservation (desiccation, mineralization, and/or waterlogging). “Table olives” are less likely to occur as charred remains because their processing does not directly involve heating; conversely, the by-product of oil production is likely to be preserved through charring, since olive processing residue (hereafter OPR) is used traditionally as a fuel in the region (e.g., Rowan 2015; Warnock 2007). Olive pits are easily recognized, with their distinctive elliptical shape, pointed apices, and irregularly veined or furrowed surface; however, their morphology can be highly variable (i.e., ranging from elliptical to rounded and/or they do not always have deep veins/furrows).

In areas where morphologically similar fruit pits occur, identification of olive pits can be problematic. For example, in Egypt paleoethnobotanical identification of olive requires caution because there is a marked overlap between sub-rounded *nabq* (*Zizyphus spina-christi* L.) pits and subelliptical olive pits, which can only be resolved by opening whole pits or examining broken fragments to determine if one chamber for the kernel (indicating *Olea europaea*) or two separate chambers (indicating *Zizyphus spina-christi*) are present. This is especially relevant to highly fragmented remains, where it is not always possible to fully reconstruct overall shape or determine if one or two chambers are present.

Olive pit dimensions also are variable, which suggests there is potential to distinguish varieties of “table” or “eating” olives from “oil production” olives. Although many conventional paleoethnobotanical studies record the dimensions of olive pits, the effect periods of drought may have on the formation of olive pits is not understood. Certainly control of archaeological context is essential if dimensions are recorded, since many deposits (i.e., fills of pits, cesspits, ditches, etc.) are likely to represent several years of different harvests, rather than a single event. The application of computer recognition programs based on fractal geometry (Bari et al. 2003) to describe the dimensions of olive pits, including the extent/degree of furrowing, have potential and may better resolve differences between “table” and “oil” olives and, possibly, varieties within each category. The effect of drought on the size and/or viability of olive pits is a moot point since propagation of olive trees

is achieved through vegetative cuttings, layers, or grafting; therefore, successful germination of “seed” is irrelevant. In essence, current olive varieties are effectively clones of early domesticated olive trees.

Paleoethnobotanical evidence for the use of OPR as fuel is known from several Mediterranean sites (e.g., Rowan 2015). The significance of angular versus rounded fractures (or breaks) in ancient olive pit fragments remains debatable. Recent work (e.g., Braadbaart, Marinova, and Sarpaki 2016) suggests that there is no reason to presume sharp angular fractures on olive pits are *not* ancient, since freshly pressed, modern OPR exhibits similar fractures; however, others have noted that rounded edges on fractures are characteristic of some archaeological OPR assemblages, and that taphonomic reasons, excavation methods, or mechanical action during flotation may explain this (e.g., Rowan 2015, 467 and footnote 24). Scanning electron microscopy and reflectance analysis of charred OPR potentially can provide information on firing temperature and/or identification of intentional charring of OPR to form charcoal fuel (Braadbaart et al. 2016).

Although olive trees can produce a crop as early as seven years after planting, trees do not reach full fruit-production maturity before at least two decades and, therefore, the decision to plant olives probably is best viewed as “planting for the next generation.” Conversely, the destruction of olive orchards would set back oleoculture in a region by at least a decade, if not two. The tendency for the production of olive oil to be a communal activity where regional harvests are both processed and pooled together, often at a central mill installation, will somewhat mitigate against variable harvests.

It is likely that Roman olive orchards represented the greatest extent of oleoculture in the ancient world (e.g., Foxhall 2007; Mattingly 1996); however, the precise limits of ancient oleoculture are currently only a matter of conjecture. In places like North Africa and the Near East, where desert conditions prevail and vegetation is less likely to obscure features, application of space-based light detection and ranging (LiDAR) could potentially reveal field systems. Certainly, Mattingly (1996, 226–228) suggests that Roman olive tree planting pits were visible in parts of Italy

and Tunisia where, shortly after World War II, aerial photography detected grids of rectilinear pits. Although cultivated and wild forms of olive pollen are indistinguishable, pollen can be identified securely to the genus *Olea* and there have been a number of palynological studies which link a substantial increase in *Olea* pollen to the introduction of large-scale olive orchards (e.g., Kaniewski et al. 2012 for Syria).

Olive wood charcoal can be problematic for reliable radiocarbon determination because olives trees are so long-lived (typically 200–300 years, although older examples are known). As a result, charcoal samples for radiocarbon determination should be based on roundwood fragments representing < 15–20 years growth. The Mediterranean/Near East is known for limited woodland and it is likely ancient societies would have been pragmatic in their selection of wood for timber and fuel, presumably dismantling and re-using timbers from structures, such as ships, for architectural and decorative wooden elements or for fuel; therefore, radiocarbon determinations from olive wood/charcoal should be treated with extreme caution, especially if not from roundwood with a known number of growth rings.

The specific identification of olive oil (i.e., as a residue on or within pottery vessels/lamps) remains problematic. Oleic acid is a diagnostic monounsaturated fatty acid in olive oil, but can be found in other plant and animal oils; moreover, unsaturated fatty acids are highly reactive, especially when exposed to water (fatty acids are water soluble and hydrolysis can break down more complex glycerides, freeing fatty acids). Recent methodological research on modern and archaeological fats using gas chromatography combustion isotope ratio mass spectrometry (GC-C-IRMS) (see GAS CHROMATOGRAPHY–MASS SPECTROMETRY (GC-MS)) has firmly established that in areas where plant oils (such as olive oil) were in use, it is not possible to securely distinguish them from porcine/ruminant adipose fats by comparing the ratio of $\Delta^{13}\text{C}$ to $\delta^{13}\text{C}_{16:0}$ (Steele, Stern, and Stott 2010).

Organic Residue Analysis

RICHARD P. EVERSLED and
MÉLANIE ROFFET-SALQUE
University of Bristol, UK

Organic residue analysis is the investigation of organic remains using instrumental analytical chemical/biochemical techniques. Such highly selective and sensitive techniques are required because the organic remains are either *amorphous*, for example fat and wax deposits, tars, pitches, or bituminous materials, or *invisible* due to their presence in complex matrices, such as surface or absorbed residues in pottery, human, or animal remains, soils/sediments, or stone objects; the components of organic residues are usually present at *trace* concentrations.

In organic residue analysis, deriving information relating to human activity in the past rests on the identification of archaeological *biomarkers*, that is, substances and biochemical compounds occurring in organic residues that can be directly related to the animals and plants humans exploited to fulfil a wide range of activities and requirements (diet, medicinal, technological, ritual, etc.) The biomarker approach relies upon matching the structures of compounds or mixtures of compounds, the latter termed “distributions,” “chemical fingerprints,” or “chemical signatures,” surviving in organic residues to the compounds and mixtures known to exist in living organisms likely to have been exploited in the past. Investigations performed since the 1970s have confirmed the survival of a wide range of compound classes at archaeological sites in association with various archaeological artifacts, biofacts, and deposits. These include lipids, proteins, DNA, and pigments, but rarely carbohydrates (although starch grains (see STARCH GRANULE ANALYSIS) are frequently reported microscopically they have yet to be chemically characterized). In the cases of ancient DNA and proteins the entire structure of the original biopolymer will rarely, if ever, survive

intact, so the structurally diagnostic biomarker entity will be fragments (sequences of DNA or building blocks and amino acids or peptides, respectively). In contrast, under favorable conditions, many small molecules, such as lipids—that is, the organic solvent soluble components of living organisms—are preserved unchanged or with minor structural alterations, making them the main targets in organic residue analysis.

Organic residue analysis requires analytical techniques able to achieve molecular-level resolution and identification. Organic materials encountered at archaeological sites are complex mixtures of biochemical components. This complexity is increased further through human activity, such as mixing biological materials, for example in food preparation, and through compositional alterations wrought by decay during burial (see TAPHONOMY). The resolution and identification of molecular structures in such mixtures demands the use of chromatographic (gas chromatography (GC) (see CHROMATOGRAPHY AND ARCHAEOLOGICAL MATERIALS ANALYSIS) and high performance liquid chromatography (HPLC) (see HIGH PERFORMANCE LIQUID CHROMATOGRAPHY (HPLC)) and mass spectrometric (MS) methods; hence, the emergence of organic residue analysis has been strongly tied to advances in instrumental methods in the modern era.

The assignment of a specific source or constituent of an organic residue based on the presence of a particular biomarker component or mixture of components demands a high degree of analytical rigor. The structures of biomarkers must be rigorously determined. Sometimes the structure of a single biomarker component is sufficient to define the origin of a constituent of an organic residue, but, more commonly, a mixture of biomarkers is used to provide chemotaxonomic-based assignments. Degradation of the components of organic residues commonly removes diagnostic compounds, leaving undiagnostic compounds or distributions, and interpretations have thus to be made with great caution and complementary information sought. Stable isotope compositions,

notably carbon ($^{13}\text{C}/^{12}\text{C}$), hydrogen ($^2\text{H}/^1\text{H}$), and nitrogen ($^{15}\text{N}/^{14}\text{N}$) isotopes, are becoming increasingly used (the latter only in the case of amino acids), providing access to information often unavailable through the structures of the compounds alone, notably metabolic and/or environmental information. The combination of molecular structures and their stable isotope compositions is most powerful in the case of the ubiquitous fatty acids that make up all fats and oils and the amino acids that comprise all proteins.

A critical aspect of organic residue analysis is consideration of the archaeological and paleoecological context. In practice, consideration of geographical location, time period, and zooarchaeological (see ZOOARCHAEOLOGY) and paleobotanical (see PALEOETHNOBOTANY) evidence can help to simplify interpretations by constraining the range of potential sources of observed biomarkers and increase the diagnostic potential of seemingly rather undiagnostic biomarkers. Further information is recorded in the makeup of organic residues in the form of altered chemical components, since certain structural transformations are predictable, thereby recording the life histories of residues derived from different technological activities or burial transformations. Thermal histories of organic residues, for example wood tar/pitch or heated animal fats/oils, are commonly recorded in the structures of specific chemical components. Often the precursor compounds are too unstable to survive over archaeological time due to their susceptibility to degradation.

All scientific investigations require experimentation to test hypotheses and support interpretations. Thus, experimental studies are an indispensable, but sometimes underused, aspect of investigations of organic residues. Experimental approaches have been applied in relation to vessel use, heating of bones and seeds, burial of pots and bones, feeding animals on controlled diet as analogs for past human diet, agricultural experiments, and sampling organisms from defined feeding experiments or modern ecosystems to provide reference databases (Evershed 2008, 2009).

Organic residues have been most widely studied in archaeological pottery, where they survive in (1) actual contents preserved in situ as vessel fills, (2) surface residues appearing as visible

residues on the exterior or interior of vessels, and (3) absorbed residues preserved within the vessel wall, invisible to the naked eye. Vessel fills are very rare, the most notable being the contents of canopic jars. Organic residues occurring on the exterior surfaces of vessels correspond to either sooting, derived from heating on a fire, or rather rare instances of applied decorations. Interior residues are often carbonized, and presumed to be residues of “cooking” failures, while visible residues in lamps can represent the remains of the fuels and wicks. Post-firing treatments are also seen, particularly as copious linings associated with Roman amphorae, presumed to have been applied to seal vessels. Visible residues have been chemically investigated and are widely used in dating programs (see DATING IN ARCHAEOLOGY and RADIOCARBON CALIBRATION AND AGE ESTIMATION), although they can become affected by post-burial or post-excavation contamination due to their exposed nature. Absorbed organic residues are the most widely studied category, since they are present in the vast majority of pottery assemblages, survive over long timescales, are protected by the ceramic fabric, and provided an integrated record of vessel use.

Biomarker investigations of organic residues in pottery date to the 1970s when the ability of clay to absorb lipids from foodstuffs processed in vessels was recognized. The results of GC/MS (see GAS CHROMATOGRAPHY-MASS SPECTROMETRY (GC-MS)) analyses of solvent extracts of powered potsherds have become the preferred approach to organic residue analysis of pottery. The introduction of GC combustion isotope ratio MS (GC-C-IRMS) in the early 1990s allowed the isotopic composition of individual compounds from archaeological extracts to be determined, which has significantly extended the utility of organic residue analysis. Studies relating to vessel use have employed replica vessels, ceramic chips, and powder to investigate both physical and chemical phenomena relating to organic residue deposition and transformations. Pottery made today provides insights into the impacts of long-term vessel use that cannot be addressed in laboratory experiments. Potsherds impregnated with organic residues have provided substrates for investigating the impacts of burial on chemical and stable isotopic compositions.

GC/MS of organic residues has revealed a wide range of biomarkers which have led to the identification of residues of an impressive range of commodities from around the world. Resins and tars have been identified through the detection of characteristic di- and triterpenes, enabling their sources to be pinpointed to tree species. The signature of beeswax consists of a complex suite of lipids, including *n*-alkanes, *n*-alkanoic acids, and alkyl (hydroxy)palmitate monoesters. Triacylglycerols (the building blocks of fats) and unsaturated fatty acids are prone to degradation, so animal fats are recognized by their saturated fatty acids. Further identification of animal fats to their source is possible using their stable carbon isotopic compositions ($\delta^{13}\text{C}$ values), enabling ruminant and nonruminant fats, and adipose and dairy fats to be distinguished. Plant-derived oils and waxes are identified based on wax esters, long-chain *n*-alkanes, *n*-alkanols, and even-numbered fatty acids. As polyunsaturated fatty acids common in fresh aquatic resources are degraded through vessel use and diagenesis, fatty acid degradation products, including vicinal dihydroxy acids, ω -(*o*-alkylphenyl)alkanoic acids, and isoprenoidal fatty acids are preferred biomarkers for identifying the organic residues of aquatic resources (e.g., fish oils).

While there was an early recognition that the analysis of lipids extracted from single vessels was a powerful method for defining pottery use, subsequent developments have seen an increase in the scale of studies, with typically tens to hundreds of potsherds from ceramic assemblages being investigated. Such studies allow subsistence practices to be unravelled at the regional, local, and even household levels and chronological trends in exploitation of resources to be explored. Paleoenviromental information can be obtained through the determination of carbon and hydrogen isotopic composition of fatty acids. Technologies involved in the production of ceramic vessels, including manufacture, finishing (e.g., sealing or decoration), and repair, can also be identified through lipid residue analyses.

The capacity to distinguish different animal fats preserved in organic residues in pottery allows the procurement and consumption of animal products to be investigated (see **FOOD RESIDUE ANALYSIS**). Questions relating to the exploitation of domestic animals for meat or milk

have been widely investigated in Europe, Eurasia, and Africa. Evidence of dairying (see **DAIRYING**) has been found in the seventh millennium BCE in northwest Anatolia, while perforated vessels from Central Europe demonstrate that cheese-making was practiced in the sixth millennium BCE. The consumption of aquatic resources has been extensively investigated, notably in Japan, where lipids from aquatic organisms have been extracted from pottery dating to 13,000 BCE.

Under favorable circumstances, lipid biomarkers have been shown to survive in soils and sediments (Bull and Evershed 2012). A critical requirement is that the deposits must have remained undisturbed by significant bioturbation from burrowing animals or human disturbance, such as plowing. Sealed tomb sediments and cave deposits with clear stratigraphies offer opportunities to study chronological changes in biomarker compositions with time. In this respect, the approaches are strongly aligned with the molecular stratigraphic principles of organic geochemistry. Indeed, investigations of lipid biomarker sediments at early hominin sites have been used for paleoenvironmental reconstructions (see **PALEOENVIRONMENTAL RECONSTRUCTION**).

Biomarker analyses of more recent archaeological sediments have provided insights into anthropogenic inputs, reflecting a range of human activities, for example waste disposal, fertilization of agricultural land, and ritual/funerary activities in tombs. An early study in the 1980s of the chemical components of sediments from a Roman fortification ditch at the Antonine Wall in Bearsden, Scotland showed high concentrations of deoxycholic acid (and 5 β -stanols) in one horizon, suggesting the ditch had been used as a drainage channel for a latrine (Knights et al. 1983). The wider utility of the approach has been demonstrated through investigations of fecal biomarkers in a range of other waste deposits. This stimulated development of the approach; building databases of biomarker 5 β -stanol and bile acid compositions of modern animals revealed the possibility for systematic identifications of the species origins of fecal deposits. Studies of soils from experimental archaeological and agricultural sites have provided important tests of the utility of steroidal biomarkers. The recognition by early pastoralists

that improved crop yields could be achieved by the use of fertilizers would have been a major step forward in the development of agriculture. Under favorable circumstances, the biomarker signals appear to be sufficiently long-lived to provide assessments of manuring practices and ancient agricultural systems ranging from the northern isles of Scotland to the Mediterranean, revealing the use of manure as fertilizer. The value of these biomarker approaches has been recognized in the study of coprolites (see COPROLITES) to provide a novel source of paleobiological and paleoecological information.

Tomb and cave sediments offer opportunities to reconstruct anthropogenic activities through the biomarkers they contain. The poor morphological preservation of organic materials in a Bronze Age tomb in Syria meant that mapping funerary activities rested significantly on sediment biomarker distributions. Remarkably, solvent extracts of sediments from a number of areas of the tomb were vivid purple in color. HPLC (see HIGH PERFORMANCE LIQUID CHROMATOGRAPHY (HPLC)), MS (see MASS SPECTROMETRY (MS)), and nuclear magnetic resonance (NMR) (see NUCLEAR MAGNETIC RESONANCE (NMR)) spectroscopy confirmed the presence of brominated derivatives of indigo and indirubin characteristic of the renowned Tyrian or Royal Purple deriving from decayed textiles, which had become incorporated into the sediments (James et al. 2009).

Organic residue analysis is undertaken on a range of human and animal remains to provide insights into biomolecular preservation, funerary practices, and ancient diet. While soft tissues rarely survive, where they do preserve (e.g., in waterlogged, desiccated, or frozen bodies) they attract a high level of interest. Early studies of lipids in bog bodies demonstrated a high level of indigeneity that was important in establishing the potential of lipid biomarkers in buried archaeological artifacts and biofacts. Beyond this, lipids offer an alternative target to proteins for radiocarbon and/or stable isotope analysis. Biomarker analyses have revealed components of bacteria involved in degradation, while the presence of mycolic acids holds potential for detecting pathogenic infections (Minnikin et al. 2012).

Skeletal remains are without question the most widely occurring class of human and animal

remains, with stable isotope and/or radiocarbon analysis routinely performed on purified collagen. This is not generally considered to fall into the area of organic residue analysis. However, there are areas where there are resonances with organic residue analysis, notably when the stable isotope compositions of individual amino acids and lipids from skeletal remains offer opportunities for refining dietary interpretations in human and other animals (Evershed 2009). The application of proteomics approaches employing MS analysis of tryptic digests to identify highly fragmented bone is a notable case where peptide sequences are the biomarker (Buckley et al. 2009).

The copious organic balms (see EMBALMING) applied to many Egyptian mummies to preserve the corpse are amorphous in nature and require the use of organic residue analysis techniques to characterize their components and offer insights into why the ancient embalmers chose specific natural products for their preservative properties or symbolic significance. The balms can be highly complex, comprising mixtures of biomarkers characteristic of coniferous (diterpenoids) and pistacia (triterpenoids) resins, beeswax, plant oils, animal fats, and so on. One of the balm components that has attracted considerable attention is natural asphalt (also referred to as petroleum bitumen). GC/MS “fingerprints” of the sterane and triterpene hydrocarbons have been used to trace the source of the bitumens to a range of sources in the Middle East, with the famous Dead Sea floating blocks being particularly prominent (Connan 1999).

Plant remains mainly survive at archaeological sites as carbonized remains. Chemical investigations have shown that carbonization destroys biomolecular integrity. However, intact biomolecules preserved in desiccated and waterlogged remains have provided insights into diagenetic processes associated with long-term burial. Carbonized cereals retain carbon and nitrogen isotope signal of manuring and irrigation regimes within their thermal altered structure, although the chemical environments within the seeds are undefined in any molecular sense. DNA in plant remains preserved under normal temperature conditions have been used in genetic studies, while lipids have found value

as comparative materials for use in the interpretation of organic residues from pottery recovered from the same sites.

The biomarker analyses discussed above fall under the heading of “targeted” analyses, since the materials are well understood and established protocols exist for the analysis of specific classes of biomarker. A range of other amorphous organic remains are preserved at archaeological sites including lumps of fat, tar, pitch, bitumen, resin, contents of glass and metal containers, deposits on stone tools, and funerary residues. Their analyses require a more classical approach involving solubility assessments, elemental analysis, and spectroscopy, among others to establish the bulk properties of the materials, revealing whether they are organic or inorganic, polymerized, and so on. Once established, appropriate analytical protocols can be designed to determine their comprehensive chemical compositions. A rare such example was a Roman tin container with its tightly fitting lid and contents, a “cream” in place. Characterization of the cream required the use of elemental analysis, loss on ignition, GC, GC/MS, pyrolysis GC/MS, GC-C-IRMS, Fourier transform infrared (FTIR) spectroscopy, iodine test, X-ray diffraction, and X-ray fluorescence to achieve a “total” analysis, revealing a mixture of animal fat and purified starch as the base for the white tin pigment cassiterite (SnO_2) (Evershed et al. 2004). The “cream” was probably a cosmetic (see PERFUMES AND COSMETICS) skin whitener.

Ostracods and Cladocerans

MANUEL R. PALACIOS-FEST

Terra Nostra Earth Sciences Research, LLC, USA

Ostracods and cladocerans are powerful tools for reconstructing past environments because of their sensitivity to environmental change. They are of particular value in understanding the history of aquatic systems manipulated by humans. Irrigation canals, reservoirs, and mill ponds or mires offer a unique opportunity to study these groups to identify the human–environment interaction. Distinction of anthropogenic from climatic signatures is critical to recognize environmental impact over time.

These aquatic forms are known as seed shrimps (ostracods) and water fleas (cladocerans), respectively. The former thrive in marine and nonmarine realms, whereas the latter are mainly restricted to freshwater (they are rarely found in salt water). In nonmarine environments ostracods are represented by the Order Podocopida (suborders Cypridocopida and Cytherocopida); therefore, this entry focuses on this group in order to aid comparison with the Order Diplostraca (suborder Cladocera). A summary of the biological, morphological, and taxonomic characteristics is given below.

Ostracods

Ostracods are microscopic crustaceans ranging in size from 0.5 to 2 mm; some may be as large as 8 mm (Figure 1). Unlike other crustaceans, they are protected by a bivalve carapace made of low-magnesium calcite (calcium carbonate). The soft body consists of reduced trunk segmentation with five to eight pairs of limbs (appendages) that they use for crawling, swimming, mating (if amphigonic: female/male; some are parthenogenetic: somatic asexual reproduction), or grabbing food from

the surrounding environment. One of the oldest and most diverse groups of crustaceans, a conservative estimate suggests there are more than 20,000 living species, 8,000 of which have been described. Known since the Ordovician (500 million years ago), ostracods may include more than 65,000 living and fossil forms. Only the hard parts (valves) survive in the archaeological record.

Nine molting stages (ecdysis) allow the organism to shed its old carapace or shell before forming a new one. Genetic make-up and the environment both influence shell morphology and ornamentation. The shells have a bean-like shape that may vary from kidney-shape, to subrectangular, subtrapezoidal, or triangular. Secreted by the epidermis, the calcium carbonate shell incorporates more than 25 minor and trace elements into the calcite structure (Bodergat 1985). Surface ornamentation may be smooth to reticulated, striated, punctuated, with or without visible pore canals, simple, or cribrated. Genders are clearly dimorphic if the species is amphigonic.

Nonmarine ostracods are sensitive to water chemistry, salinity, temperature, and dissolved oxygen, among other parameters. They occur in freshwater, brackish, and brine conditions in lakes, ponds, wetlands, springs, and streams, including irrigation canals and reservoirs (Palacios-Fest 2002). Altitude and latitude are also important factors controlling the species' geographic distribution. Based upon their ecological requirements, it is possible to use this group in paleoecological reconstructions to understand the human–environment interaction. The reader is encouraged to consult Horne, Cohen, and Martens (2002) for further details on ostracod anatomy and ecology.

Cladocerans

The Cladocera include four infra-orders—Anomopoda, Ctenopoda, Onychopoda, and Haplopoda (according to the Integrated Taxonomic Information System: www.itis.gov). To date, about 620 taxa are estimated to represent the

Cladocera, in sharp contrast to ostracod diversity. Extant since the Paleozoic, the fossil record is better documented from the Mid-Mesozoic to the present (Kittel et al. 2014).

Cladocerans are microcrustaceans. They range in size from 0.2 to 6 mm and up to 18 mm (Forró et al. 2008) (Figure 2). The soft body is encapsulated within the secreted bivalve shell folded in half, made of lipids, slimes, chitin, and pigments that may uptake some minor

and trace elements like phosphorus, calcium, strontium, sodium, and iron (Smirnov 2014). Like other arthropods, cladocerans grow by molting their exoskeleton up to seven times or less (two for chydrids) (Dodson and Frey 2001). Even though sexual reproduction may occasionally occur, they are mostly parthenogenetic; this is known as cyclical parthenogenesis. Environmental parameters play a role in controlling species abundance and distribution.

Some species are eurytopic (found in a wide range of environmental conditions), while others are stenotopic (found in restricted environments). The group occurs in lakes, ponds, and artificial mill ponds where slow-flowing waters prevail. They are also found in fast-flowing systems (Kittel et al. 2014). An important component of

the trophic chain, cladoceran populations are affected more by the presence of phytoplankton and predators than by water chemistry, salinity, or temperature, even though the latter appears to influence body size and reproduction. Most species form part of the zooplankton living in open water. Other species are nektonic, thriving

in bottom vegetation. For a detailed description of this group the reader is encouraged to consult Dodson and Frey (2001).

Like ostracods, cladocerans can be used to reconstruct past environments associated with human activity (see PALEOENVIRONMENTAL RECONSTRUCTION). Among the most useful approaches is the identification of lake status, such as climate changes, trophic oscillations, acidification, and water-level changes.

Sample preparation

Ostracods and cladocerans require different sample preparation procedures. As ostracods possess a hard calcium carbonate shell, extracting them from the sediments is somewhat easier than extracting cladoceran chitinous shell from the same materials. Ostracods may be removed from sediments through a simple procedure that consists of disaggregating the sediments in boiling soapy water, washing through a gentle shower, and letting the sample air-dry to allow the valves to be picked out with a fine brush using a low-power microscope (Palacios-Fest 1994).

Cladoceran chitin is quite resistant to many chemicals (except acetolysis); therefore, it is possible to follow similar procedures to those used in pollen analysis (Frey 1986, 669–675). Cladocerans can be extracted from samples examined for other biological remains such as plant macrofossils and insects (see SAMPLING IN ENVIRONMENTAL STUDIES). A compound light binocular microscope is used for sample examination. The slides contain not only complete exoskeletons but also their fragments, mainly resulting from predation or decomposition in situ. As in pollen analysis, it is convenient to prepare reference collections of whole organisms and their shells to compare with unknown specimens.

Quantitative analysis is necessary for both ostracods and cladocerans in order to reconstruct past environments. Total and relative abundances and species diversity are recorded. If possible, it is also important to record the taphonomic parameters (e.g., fragmentation, abrasion, disarticulation (for ostracods), and adulthood ratios).

Case studies

Las Capas archaeological site (AZ AA:12:111 (ASM)) and its associated canals (site AZ AA:12:753 (ASM)) offer the first refined reconstruction of a complex irrigation canal network operating during the San Pedro phase of the Early Agricultural period (1200 BCE–50 CE). The site is located along the Santa Cruz River in Tucson, Arizona, the United States. Geochemical data, stable isotopes ($\delta^{18}\text{O}$ and $\delta^{13}\text{C}$), and trace element molar ratios (Mg/Ca_v and Sr/Ca_v) were obtained from the valves of *Ilyocypris bradyi*, the most common and abundant ostracod in the canal network. The signatures obtained provided a unique record of ancient irrigation networks that allowed us to infer water-use patterns and how humans impacted the environment 3,000 years ago (Palacios-Fest 1994, 2002).

Water evaporation from the Santa Cruz River to the agricultural fields was tracked. Three trends were estimated assuming water temperatures ranged between 15 and 25 °C (Figure 1). Feature 42, the main canal, showed the lowest evaporation values. Feature 21, a distribution canal, displayed a slight increase in the aridity index observed at any given temperature. Surprisingly, in Feature 27, the lateral canal, the aridity index varied randomly, suggesting periodic canal operation in contrast to the long-term flow indicated by the other two canals, suggesting that terminal canals, which are temporary, operated at periods of fresher water input.

Human impact in central Poland has been identified through the study of cladocerans and pollen from the Świerczyna mire in the Grabia River valley (Pawlowski et al. 2015) (Figure 2). The record spans 9,000 years, with Cladocera providing a valuable environmental signature not easily identified by other geological methods. In their study, Pawlowski et al. (2015) found six cladoceran assemblage zones based on the occurrence of species belonging to three families (Bosminidae, Daphnidae, and Chydoridae). The record is broken at times due to water-level fluctuations.

Water-level increase was associated with episodes of climate change that the authors also related to human activity in the area. The Grabia River moved a higher volume of water in

response to increasing rainfall but also as a result of higher rates of deforestation and soil erosion that affected the mire, resulting in corresponding changes in cladoceran frequency and diversity. Based on these organisms' chronostratigraphic records, four phases of wet climate conditions were recorded in Świerczyna mire (5800–550 BCE, 4500–4300 BCE, 4200–3800 BCE, and 400 CE). Anthropogenic influence was stronger in several phases too (1300 CE, 1500 CE, and 1650 CE), when human activity and wet climate left a clear imprint, particularly during the Middle Ages and in the last century.

Future prospects

Incorporating ostracod and cladoceran analysis with geoarchaeology will improve our ability to understand human–environment relations. Other research approaches such as investigations using shell chemistry may add more to our comprehension of environmental change in the future.

Paleoethnobotany

ROBERT N. SPENGLER III

Max Planck Institute for the Science of Human History, Germany

Paleoethnobotany refers to the scientific study of the interaction between humans and plants in the past; this includes the study of human impacts on the environment, how the environment directed human practice, and cultural uses of plants. It is simultaneously a subfield of archaeology and ethnobotany, which, in turn, are subfields of anthropology (in the American academic system) and botany or the plant sciences, respectively. In this sense, a paleoethnobotanist studies past human culture and plant life. In practice, this often consists of studying the remains of plants in archaeological sites, by a specialist, who draws upon methods and theoretical frameworks from both the biological and social sciences. In essence, paleoethnobotany is at the intersection of the interplay between living organisms and human culture. The term paleoethnobotany is also used synonymously with archaeobotany and advocates a multidisciplinary approach to studying human history. Specialists are required to mingle laboratory-produced data with historical texts, ethnographic analogies, cross-cultural comparisons, and a wide range of archaeobotanical data that are extracted from archaeological contexts, including ancient crafts made from plants, impressions of seeds and plant parts in ceramics or mudbrick, remains of plants in human paleofeces or in the stomach contents of preserved bodies, as well as artifacts or tools used to process or cultivate plants, such as grinding stones, farming tools, woodworking tools, digging sticks, loom weights or spindle whirles, and irrigation structures.

The most widely studied topic within the field relates to human paleodiet, and how humans cultivated or foraged for, harvested, and consumed plants in the past, as well as what kinds of plants they chose to eat. In

addition, some of the most widely publicized questions in the field surround the topic of plant domestication—including when certain plants were domesticated, how long this process took, where the domestication process took place, and why humans initiated the process. The origins-of-agriculture debate remains one of the most lively topics of inquiry in the archaeological sciences. Indeed, the plants that were morphologically domesticated as a response to human cultural practice express the closest coevolutionary relationship to humans, and, in studying them, scholars are looking at the deepest interrelationship that humans have with plants. There is also a wide array of research topics beyond plant cultivation; these include questions relating to how humans through time have impacted the environment that they live in, often dramatically reshaping plant communities, such as in agricultural fields or managed forests. All humans continually impact the plant communities around them, reshaping entire ecosystems and altering niches. In addition, plants are used for a range of cultural purposes beyond food and drink, including architectural construction material, textile and basket production, clothing, rope, fiber, and thread, weapons, hunting equipment, fishing nets and tackle, boat construction, ornamentation and art, dyes and paints, medicine, cosmetics, bedding, kitchen and household utensils and furnishings, fuel, ritual practices, and displays of status, identity, and aesthetics.

While the field is rapidly branching out into new methodological realms, including genetics (using ancient and modern DNA; see GENETICS: ANCIENT), isotope studies (see ISOTOPES), phytochemistry, proteomics, and other biomarkers, it has traditionally focused on the morphological identification of ancient plant remains. Many scholars in the field further subdivide paleoethnobotany into two primary branches based on methodological approaches: microbotanical and macrobotanical methods. The latter deals with all archaeobotanical remains that are large enough to see with the human eye, even if the identification of these remains requires magnification, whereas

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0433

microbotanical approaches deal with plant remains that can only be seen with high-power magnification—phytoliths, pollen, and starch grains. Both methodological branches rely on morphological identification at a microscope; however, macrobotanical studies principally use dissecting microscopes with magnifications up to 50 $\times$, whereas microbotanical approaches generally use reflected or transmitted light microscopes at magnifications up to 1,000 $\times$. The field is largely quantitative, relying on the abundance and density of specific categories of plant remains in specific archaeological contexts. These counts and ratios go beyond simple observations of presence and absence and allow the specialist to determine cultural practices relating to plant use in specific areas of an archaeological site.

Plant tissue does not readily preserve; hence the archaeological recovery of these remains only occurs when specific depositional and taphonomic processes are met. Plants are consumed by fungi, including mold, animals, including insects, and microorganisms; only when the biological deterioration of these plants is prevented will they preserve in archaeological contexts. The majority of the macrobotanical remains recovered from archaeological sites have been burnt—carbonized or charred—either accidentally, such as by storage areas catching fire, or deliberately, when used as fuel or as discarded trash in a cooking hearth, resulting in their long-term preservation in anthropogenic sediments. Plant remains that have been carbonized will no longer deteriorate (rot) at the same rate as uncarbonized remains, as carbon is largely inert and not subject to biological or chemical attack, though such remains are vulnerable to physical and chemical weathering (see Miksicek 1987). Plant parts, such as seeds and fruit structures, can be preserved through other vectors, through which chemical, biological, and mechanical deterioration is halted or slowed, such as being incorporated into an anoxic environment (e.g., permanently waterlogged conditions or deep burial), or when desiccated, exposed to the corrosion products of metals, frozen, or through mineral replacement (e.g., calcium-phosphate replacement; see FORMATION PROCESSES).

The most widely studied category of macrobotanical remains includes seeds and fruit parts, such as nut shells; other archaeological remains of

plants include carbonized wood (see CHARCOAL AND WOOD ANALYSIS), pedicles, stems, textiles, and fibers (see TEXTILES), roots and underground storage organs, parenchyma tissue, and in some cases even leaves and floral structures. Carbonized macrobotanical remains are usually recovered from archaeological sites by means of a flotation/water separation system. There are several ways that excavators and specialists approach the systematic removal of botanical remains from anthropogenic sediments (for a discussion see Fritz 2005; Watson 1976); collectively, these methods are referred to as flotation. Flotation methods rely on buoyancy to mechanically separate carbonized plant remains from the soil matrix, dirt, rock, or other inorganic materials. Sieving is then used to remove all material below the target particle size.

In cases where macrobotanical remains did not preserve or as a complement to other lines of evidence, paleoethnobotanists can turn to microbotanical data, such as pollen. The study of pollen, or palynology (see PALYNOLOGY), has gone hand-in-hand with paleoclimatic studies for nearly a century. The most important use of pollen data for paleoethnobotanical purposes is to help elucidate changes in settlement patterns or possible anthropogenic impacts on vegetation cover. While pollen data are still most often used by scholars to reconstruct ancient vegetation communities, the data can also be used to understand aspects of human activities in the past. Pollen studies are sometimes conducted on sediments in archaeological sites, under the assumption that concentrations of pollen from economically significant plants may indicate processing areas or areas where flowers were concentrated, such as through a funerary offering.

Phytoliths (see PHYTOLITH ANALYSIS) are silica-based structures that form through the deposition of inorganic material inside or between plant cell walls. The particles serve the function of both providing structural support and reducing herbivory for the plant. Because the particles are inorganic, they are not subject to the same processes of biological deterioration as other plant remains and can preserve in situations where other organic material does not. However, not all plants produce the same abundance of phytoliths, nor are the same densities of these deposits produced in all parts of the plant. In

many cases, the morphology of the phytoliths is distinct to a specific clade of plants, allowing phytolith experts to identify categories of plant remains in archaeological sites, even if macrobotanical remains do not preserve. One of the most significant aspects of phytolith studies is the fact that these siliceous particles form in the leaves and stems of plants, leaving a signature of plant parts that are rarely preserved as charred remains.

Starch grains (see STARCH GRANULE ANALYSIS) are small granules of carbohydrates that form inside certain parts of some plants. They are commonly found in the fruits, roots, and seeds of many plants; in some cases, starch is stored in the leaves and stems of plants as well. While it is not exactly clear how carbon-based particles preserve in archaeological contexts, they have been recovered from dental calculus, ceramic sherds, organic materials, sediments, and stone tools. Starch grains often provide a direct indication of food processing, when found on grinding stones, or food consumption, when found in dental calculus or in cooking pots and on processing tools.

All of the methods mentioned above have positive and negative aspects and, therefore, they are best implemented in unison. Macrobotanical, rather than microbotanical, studies provide the most reliable line of evidence, and, in most cases, macrobotanical remains can be identified to a more specific cladistic level, often to species. However, phytoliths can be used in cases where macrobotanical remains do not preserve. Many studies have shown that these methods are complementary and produce data that highlight different aspects of the plants used by people in the past. For example, the glumes or chaff of grain crops contain phytoliths, and, therefore, finding high densities of chaff phytoliths in one area of a site may indicate that it was a crop-processing location. In addition, starch grains on archaeological tools and grinding stones have allowed scholars to determine what the tools were used for. Integrated or multivariant datasets are becoming increasingly more prevalent in the field, producing the most holistic picture possible. In addition, ethnoarchaeology has been tied closely to archaeobotanical interpretation for many decades. For example, studying what plant remains are found in recently abandoned pastoralist campsites in West Asia has helped scholars determine what vectors ancient plants

followed to ultimately end up in archaeobotanical assemblages (Spengler 2015). By studying these modern analogies, scholars can hypothesize whether specific seeds were introduced to a site as human food or if they followed another vector into the site, such as through dung or sod burning as fuel, through crop-processing to remove seeds from field weeds, incorporated into bedding or roofing material, or as seed rain—among a wide range of other possible vectors.

There are many historical overviews of the field, and the reader interested in understanding the development of paleoethnobotany should turn to sources such as Pearsall (2015) and Watson (1997). Pearsall (2015) suggests that the field was largely formalized into a system of inquiry with an article published by Volney H. Jones (1941) titled “The Nature and Scope of Ethnobotany”. In this article, Jones uses a broad definition for the field, noting that it centers on the study of the interrelationship of plants and humans; he also emphasized the interdisciplinary nature of the field, which is still one of its hallmarks today. While the systematic targeting and recovery of archaeobotanical remains may only date back to the 1940s, botanists have been recording and identifying plants in archaeological sites since the nineteenth century, with Kunth’s 1826 study of remains in Egyptian burials and Heer’s 1866 study of plant remains from waterlogged villages in the mountains of Switzerland. Furthermore, large-scale multidisciplinary expeditions, with scientific specialists including botanists on staff, have been undertaken for over a century, such as Pumpelly’s 1904 expedition to Anau in Turkmenistan. The term paleoethnobotany was first used in 1959 by Hans Helbaek; and Richard Ford’s definition from 1979 is still widely used today—“the analysis and interpretation of the direct interrelationship between humans and plants for whatever purpose as manifested in the archaeological record” (Ford 1979, 286). Over the past half century, the field has moved forward with new methods and technology in the laboratory, at the excavation site, and during data interpretation. As new technology and scientific methods are introduced, the questions that archaeobotanists are asking have become increasingly complex. Research questions addressed by specialists, by definition, deal with food and ecology, which

are inseparably intertwined with sociopolitical organization, ideology, and identity, exchange, kinship, adaptability, and ecosystem engineering. However, in the past few years, scholars have increasingly embraced a range of previously overlooked questions; one of the most intriguing of these is the topic of cuisine. These specialists are readily stepping beyond simple tallies of plant remains and instead discussing how the remains came together in a culinary tradition. In order to achieve this goal, they need to incorporate other archaeological artifacts, including tools and cooking pots, human osteological studies, and isotope analyses, as well as zooarchaeological data.

Plant domestication continues to be one of the most prominent areas of investigation (Langlie et al. 2014) (see DOMESTICATION), and with the incorporation of genetic approaches since mid-2000 scientists have largely rewritten what we know about the origins of our domesticated plants. For example, many specialists are looking beyond the idea of simple domestication models that rely on single centers of domestication and rapid domestication events, recognizing that many plants were domesticated multiple times and that this process may have taken several millennia. Increasing scientific investigation is also showing that the transition between hunting and gathering to farming is not a simple one and that many foragers also grew crops. Similarly, the introduction of archaeobotanical methods into parts of the world and time periods where archaeologists did not expect to find farming has been changing scholarship, notably in areas of Eurasia that were thought to be largely dominated by nomadic populations (e.g., Spengler 2015). In addition, many archaeobotanists are recognizing that questions concerning dissemination of these plants are as important as the identification of the original domestication; scholars are focusing more on plant spread and exchange. Other popular topics of investigation include human health and nutrition, plant pathologies associated with cultivation, the study of the spread of invasive species, the ramifications of deforestation, and the effects of global climate change in the long term. Furthermore, scientists are turning more towards multivariate statistics (see MULTIVARIATE ANALYSIS) and direct integration of plant and animal remains. Archaeologists acknowledge that plants are fundamental to human life and,

therefore, a comprehensive picture of human societies of the past cannot be drawn without the incorporation of paleoethnobotanical methods. As a result of the developments in the field of paleoethnobotany over the past half century, specialists are readily incorporated into excavations and the data they produce are held on par with other lines of archaeological investigation.

Paleoethnobotany and Ancient DNA Analysis

LOGAN KISTLER

Smithsonian Institution, National Museum of Natural History, USA

Ancient DNA allows researchers to study changes in populations of humans, plants, and animals over archaeological time spans by analyzing genetic information from archaeological tissues (see [SEQUENCING DNA](#)). Combined with paleoethnobotany (see [PALEOETHNOBOTANY](#))—the study and interpretation of archaeological plants—ancient DNA can be used to investigate the domestication (see [DOMESTICATION](#)) of plants and the transition to agriculture, the human-mediated dispersal of plant species into new ecosystems and between societies, the evolution of plants as crops under human influences, food production systems, evolutionary ecology, and other topics at the interface of archaeology, botany, and ecology. In total, ancient plant DNA research provides real-time insight into evolution, demography, and population biology on the human landscape (see [GENETICS: ANCIENT](#) and [GENOMICS: ANCIENT](#)).

Ancient DNA fundamentals, applications, and challenges

DNA is the complex biomolecule that encodes an organism's fundamental organization, development, and physiology. The sequence of the four nucleotide bases that make up DNA (adenine, cytosine, guanine, and thymine: A, C, G, and T) not only underlies the structure and function of biological systems but also provides detailed insight into evolutionary relationships and demographic histories of organisms and species. Working with modern DNA sequence data can provide a wealth of information at a single time point of sampling, but integrating ancient DNA

is especially valuable in that it adds important time depth to analyses of population processes by allowing real-time insight into phenomena such as plant domestication.

By comparison with modern-only genetic approaches, ancient DNA analysis offers several benefits. First, ancient DNA harbors extinct variation no longer present in modern organisms. In domestic plants, for example, loss of diversity over time is an expected consequence of human cultivation, breeding, and management. By analyzing DNA from ancient plants alongside DNA from modern ones, these long-term trends in genetic diversity and structure can be directly examined across multiple time points instead of being inferred through the genomic vestiges of these population processes. Assessing the genomic characteristics of ancient crops falling on the continuum between wild types and modern cultivars can provide tremendous insight into the biological, ecological, and cultural processes associated with shifts in food production strategies.

Second, sampling DNA across the time frame of the archaeological record allows the unraveling of the myriad influences of various human activities on the genetic legacies of plants in human environments. In the long term, trade, breeding, and gene flow following plant domestication dramatically shape plant biology and genetics. More recently, economic development, population growth, rapid travel and communication, and similar effects of industrialization and globalization have massively altered the genetic landscape of global food production, and in many cases may overprint the genetic legacy of the plants that are historically important to humans. Currently, worldwide food calories are derived from a small number of cultivars in a handful of staple species—most importantly maize, rice, wheat, potatoes, sorghum, and cassava. The modern varieties of global importance often result from breeding programs that focus on productivity and predictable yield, whereas the evolution of these species alongside human cultivators is best understood by analyzing traditional landraces and archaeological materials. In short, modern

plants important to humans are the result of diverse cultural and ecological histories, and ancient DNA analysis provides a direct mechanism to interrogate the strata of plants' unique legacies, in collaboration with paleoethnobotany.

Third, ancient DNA can provide a powerful means to resolve paleoethnobotanical uncertainty and test hypotheses related to ancient plant remains. Where morphological and anatomical characters are inconclusive, taxonomic identifications can be refined through genetic analysis of ancient tissues with suitable preservation. Further, if paleoethnobotanical analysis reveals morphological changes over time that are consistent with, for example, either rapid *in situ* evolution or replacement by a nonnative variety, these two scenarios can be probed through a population genetic hypothesis-testing framework. In total, ancient DNA can provide a data layer for complementing paleoethnobotanical analysis where information on genetic relationships and evolution can enrich the understanding of a region, time period, or plant taxon.

When compared with modern molecular biology, ancient DNA research involves two primary challenges: it is highly degraded; and it is highly prone to contamination by modern sources.

In living cells, enzymatic repair mechanisms are responsible for maintaining the structure and biochemical integrity of the DNA molecule. When replication error or the actions of DNA-degrading enzymes alter the sequence or nick the DNA backbone *in vivo*, for example, these repair mechanisms are evolved to restore DNA to working order and to ensure relatively uninterrupted cellular function. Thus DNA strands sampled from living or freshly deceased tissue can be recovered at hundreds of thousands of base pairs (bp) in length, and their sequences can be recovered with high fidelity. In ancient tissues, these repair mechanisms have long since ceased functioning in their protective role, and any remaining DNA is highly degraded. Over time, DNA is physically broken down into small fragments; an herbarium specimen or a desiccated seed typically has only a very small proportion of fragments greater than 100 bp, with the mode of recoverable fragments closer to 30 bp. This poses challenges both for recovering and, later, for analyzing ancient DNA. Moreover, postmortem chemical damage to individual

nucleotides accumulates over time in ancient tissue, and must be corrected computationally. Further, the majority of DNA fragments seem to be totally lost to damage or leaching, so that endogenous DNA concentration is much lower in ancient tissues than in their modern equivalents.

DNA degradation is a complex process with several environmental correlates, and the conditions for DNA survival are only understood at a rudimentary level. In general, however, samples from cool, dry, and thermally stable preservational contexts offer the best chances for successful ancient DNA recovery. Sample age is strongly linked with recoverable DNA content, and the oldest widely accepted DNA is from permafrost-preserved horse bone roughly half a million years old. For ancient plant samples, the best sites for DNA recovery tend to be dry caves, rock-shelters, and open sites in extremely arid climates such as coastal Peru and the southwestern United States. Waterlogged plant remains—from both saline and freshwater environments—have also produced DNA suitable for genomic analysis. Charred remains, by far the majority of paleoethnobotanical materials, are unfortunately very poor vessels for DNA preservation. Incomplete carbonization leaving some preserved organic matter has produced usable DNA in several experiments, but with charred plant remains a few successes are usually accompanied by many failed attempts. A wide variety of ancient materials have successfully yielded plant DNA under the right preservational circumstances, including starchy and oily seeds, maize cobs, grape pips, herbarium leaf and inflorescence tissue, fruit stones, peanut shells, squash and gourd rinds, wood, other vegetative structures, and even some sediments and residues. As yet, phytoliths and starch grains have not produced ancient nucleic acids, but DNA has been analyzed from pollen cores recovered from lake deposits.

Because of the degraded and low-copy nature of ancient DNA, contamination of tissues and experimental setups by high-quality modern DNA are a serious risk. Early studies reporting geologically ancient DNA recovery—including of dinosaur fossils and plant tissues preserved in amber—were ultimately attributed to contamination rather than extraordinary DNA preservation. However, these early issues with ancient DNA research led to the formalization of

criteria to detect, prevent, and mitigate the effects of contamination (Cooper and Poinar 2000). Standard protocols include working with ancient tissues in a lab that is physically separate from modern genetics experiments, wearing full-body personal protective equipment, disinfecting surfaces extensively with bleach and/or ultraviolet radiation, using “negative controls” in parallel with experimental tissue preparations to detect laboratory contamination, and taking other technical steps aimed at preventing contamination. Contamination can be especially problematic in human and archaic hominin research, where experiments can be compromised by researchers’ own DNA. However, ancient plant DNA contamination is also pernicious owing to the sheer environmental ubiquity of plants.

A timeline of ancient DNA and paleoethnobotany

In 1984 the first successful ancient DNA experiment was published in *Nature*; it reported a few hundred base pairs of sequence data from an extinct zebra relative called quagga, preserved in 140-year-old muscle tissue from a museum specimen (Higuchi et al. 1984; see ZOOARCHAEOLOGY AND ANCIENT DNA). This success laid essential groundwork by establishing that postmortem DNA could survive historic time spans; and it raised the realistic prospect of archaeologically and even geologically ancient DNA recovery. Following this proof of concept, the first methodological breakthrough for ancient DNA research was the Nobel Prize-winning development of the polymerase chain reaction (PCR), which allowed precise enzymatic amplification of target DNA fragments. PCR can be used to amplify extremely low quantities of target DNA, theoretically permitting a single copy of a rare target to be recovered for analysis. For this reason, PCR is especially useful for isolating target fragments from mixtures of degraded endogenous and environmental DNA typical in ancient tissues. The PCR method was developed in 1983 and first applied to ancient DNA in 1988 (Pääbo, Gifford, and Wilson 1988), with the successful amplification and direct sequencing of mitochondrial DNA fragments from ancient human tissue. In contrast with previous cloning and hybridization-based

methods for targeted DNA recovery, PCR is highly sensitive and can be deployed with a wide range of species and target DNA conditions. In total, PCR not only revolutionized molecular genetics as a whole, but dominated ancient DNA research for over two decades.

In recent years, PCR and amplicon sequencing have largely been supplanted by the second major breakthrough in the ancient DNA field: genomic technologies that permit sequencing millions of DNA fragments in parallel rather than narrowly targeted individual molecules. The first ancient genome—low-coverage whole-genome sequencing of a woolly mammoth using the Roche 454 platform—was completed in 2008, and the period since has seen exponential growth in the number of studies that apply genomic technologies to ancient DNA-based experiments. While PCR and targeted sequencing allow hypothesis-driven studies at the population level, PCR-based ancient datasets are fundamentally limited to the informative value of a few small fragments across dozens or hundreds of samples. On the other hand, genomic data facilitate a deep dive into the evolutionary, population genetic, and demographic context of ancient organisms through the recovery of very large datasets from individual tissue samples. For this reason, PCR and direct sequencing are rapidly giving way to genomic methodologies in ancient DNA research design across all fields, including plant research.

Since the first ancient DNA studies in the mid-1980s, plant specimens have been analyzed alongside human and animal tissues, and the field of plant archaeogenetics has developed and matured alongside ancient DNA research as a whole. In 1985, simple gel electrophoresis tests revealed the preservation of nucleic acids in a range of herbarium specimens and other desiccated plant tissues (Rogers and Bendich 1985). Although this approach was not conclusive as to whether the DNA detected was from plant tissues or from external sources such as microbes, this was the “quagga” moment for plant research; these experiments demonstrated fundamental tractability and set the stage for the exploration of the biological interface of plant–human interactions through archaeobotanical DNA. Throughout the 1990s, several studies sought to establish the limits of preservation of DNA in ancient plant tissues—including the plausibility

of retrieving DNA from charred seeds. Other early ancient plant DNA studies began probing for molecular signals in plant tissues that would address specific questions raised by archaeology. Early archaeological targets included aspects of the domestication and dispersal of maize (see MAIZE) and taxonomic identification in grain assemblages—a long-standing question for the spread of the Old World Neolithic crops.

Palmer, Smith, and Allaby (2012) review roughly a hundred ancient plant DNA publications from the PCR-dominated era of research—a nearly exhaustive treatment of the literature across tissue types and research orientations that illustrates the diversity of plant research from this period. They note that the most extensively archaeologically characterized gene of the PCR era is wheat (see WHEAT) glutenin (Glu). The genes in this family are generally compact, and therefore reasonably recoverable using very short fragments. More importantly, Glu is informative as to the movements and complex hybridization history of wheats in the Near East, which makes it a prime target for the application of genetic methods to archaeobotanical questions.

The genomic revolution reached ancient plant DNA research shortly after the 2008 woolly mammoth genome, when a method known as target capture was applied to maize and published as a methods comparison in 2011 (Ávila-Arcos et al. 2011). This technique, which uses synthetic RNA probes to isolate large panels of target DNA for efficient sequencing on a genomic platform, has since become a staple of the archaeogenomic toolkit. While this experiment first introduced genomic technology with ancient plants, an analysis of ancient cotton genomes the following year marks the beginning of hypothesis-driven genomics in archaeological plants (Palmer, Clapham et al. 2012).

The interceding years have seen a rapid growth of plant archaeogenomics using a suite of methods for diverse purposes and on a variety of tissue types. Genomic analysis in plants can present biological challenges not typical of human or animal studies. Broadly, plant genomes are of an order of magnitude more variable than animal genomes, and this adds layers of complexity for archaeological plant genomics. The human genome comprises roughly 3.2 billion base pairs (Gbp); this makes it typical of mammals,

which vary from ~2 Gbp in some bat species to ~8 Gbp in vizcacha rats, mammalian outliers. By comparison, domesticated members of the grass family alone range from 0.4 Gbp (in rice) to 15 Gbp (in bread wheat), a roughly tenfold greater span than the entire range of variation in mammal species. Moreover, animals are nearly all diploid—carrying two chromosome copies in each cell. Plant genomes also vary widely in this regard, whole genome duplication and hybridization leading to numerous instances of polyploidy throughout evolutionary history. Polyploidy occurs even in the compressed evolutionary trajectory of domestication—common bread wheat (*Triticum aestivum*) carries three chromosome copies from each parent, each acquired from a different species through hybridization during the process of domestication. This level of variation illustrates a tremendous capacity for genome restructuring and genomic plasticity that is not paralleled in most animals, which raises challenges to research design but also valuable targets for analyzing the complexities of plant systems on the human landscape.

At present, a small number of whole-genome studies from ancient plants have been published, and many more are in progress. The cost of data collection has decreased substantially in recent years, and methods for improved ancient DNA recovery and analysis have created new opportunities for ambitious research programs. Researchers are now deploying genomic methods to revisit archaeobotanical questions that were incompletely treated in the PCR era, and the range of testable hypotheses has expanded immeasurably with the breadth of data now being produced. Epigenomic profiles—chemical modification patterns in DNA, related to gene regulation and expression—have recently been shown to survive in archaeological material. The field of archaeoepigenomics, new and so far almost completely unexplored, offers potential for unprecedented insight into ancient plant–human interactions. Finally, modern plant genomics is itself a rapidly evolving discipline providing essential context and comparative data for archaeogenomic research, with a swiftly growing volume and diversity of available plant genomic resources.

Paleoethnobotany and Stable Isotopes

LISA LODWICK and ELIZABETH STROUD
University of Oxford, UK

Stable isotope analysis of paleoethnobotanical remains provides a new technique to investigate crop cultivation, paleodiet, paleoclimate, and food exchange. The main elements investigated have been carbon and nitrogen, alongside hydrogen and oxygen for wood. The technique has principally been applied to cereal crops, mainly wheat and barley, but also maize, millets, pulses, rice, and sorghum. Application of the technique has been global in reach, and major studies have taken place in Europe and the Middle East on paleoethnobotanical remains from sites ranging from the Neolithic to the Roman period.

Stable isotope analysis of plant remains from archaeological sites was first undertaken in the 1980s, although plant remains have long been used for radiocarbon dating. During the 1990s, work concentrated on stable carbon isotopes, both studies of modern plants, and the investigation of water inputs to crops in the ancient Mediterranean. The 2000s saw a resurgence of interest in the investigation of plant remains, due to a combination of the increased understanding of the way isotopic ratios are affected by plant physiology and the application of the method to archaeological questions. Particular archaeological issues of long-standing concern include understanding crop cultivation conditions and the need to create plant baseline data for paleodiet studies. The large-scale application of isotopic approaches to archaeological plant remains over the last decade has been facilitated by the rigorous investigation of isotopic variation in modern field studies, taphonomy, sampling, and pre-treatment.

The application of plant isotopic ratios relies on knowledge of the ratios of specific isotopes in the soil or plant tissues. Photosynthesis discriminates against the heavier ^{13}C in preference for the

lighter ^{12}C isotope. The level of discrimination is affected by stomatal opening, and produces recordable separation in C_3 plants based on water status. Stable nitrogen isotope ratios of plant remains are linked to soil N of the growth medium, and can be used to infer potential addition of manure. The lighter ^{14}N isotope is preferentially lost from manure as volatile gaseous ammonia, resulting in ammonium enriched in ^{15}N , which is then taken up by plants.

Experimental studies have proven that environmental conditions have a measurable impact on stable isotopic ratios within plants. Field studies in the United Kingdom, Denmark, and Germany have shown that intensively manured cereal grains can have $\delta^{15}\text{N}$ values of around 8‰ higher than unmanured crops (Bogaard et al. 2013). However, ^{15}N enrichment in the soil can also be caused by wetland denitrification, salinity, aridity, microbial activity, and recent clearance. Experimental evidence from Morocco indicates that the aridity effect can be countered by factoring in annual rainfall and also through consideration of the $\delta^{15}\text{N}$ value of non-manured vegetation, extrapolated from wild herbivore $\delta^{15}\text{N}$. In relation to carbon, the $\Delta^{13}\text{C}$ notation is commonly used as it takes into account past fluctuations in atmospheric $\delta^{13}\text{C}$ values when extrapolating water status; $\delta^{13}\text{C}$ measurements from ice core records have been interpolated using the AIRCO2_LOESS system to calculate the $\delta^{13}\text{C}$ of air at different time periods allowing the conversion of $\delta^{13}\text{C}$ to $\Delta^{13}\text{C}$. Field studies of irrigated and un-irrigated crops in Syria and ethnobotanical studies of farms in Spain, Greece, and Jordan have established species-specific watering thresholds; for example, well-watered wheat has $\Delta^{13}\text{C}$ values of about 17‰ (Wallace et al. 2015). While there is consensus in the mechanisms behind isotopic fractionation, debate continues as to the interpretation of observed $\Delta^{13}\text{C}$ values.

The most recent applications of crop stable isotopic ratios have incorporated increasingly rigorous sampling and pre-treatment methodologies, which have further demonstrated that

DOI: 10.1002/9781119188230.saseas0436

the isotopic ratios measured in grains are a reflection of variations in past growing conditions. A statistical understanding of the potential variation within cereal ears and within fields has been calculated experimentally. Approaches to sampling differ between those who analyze single cereal grains, in order to account for seed-level variability, and those who analyze bulk samples of ten grains or more, in order to understand field-level variability. Numerous experimental studies into the effect of charring on isotopic ratios have concluded that minor variations are produced in $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$, an important factor to consider when comparing results with collagen-derived isotopic ratios (see ZOOARCHAEOLOGY AND STABLE ISOTOPES). Cereal grains and other crop remains are extracted from flotation samples taken from contexts or stratigraphic units excavated at an archaeological site. Contamination from carbonates, nitrates, and humic acid during burial can be removed through a range of pre-treatment techniques, usually including washing with HCl and NaOH. The use of Fourier transform infrared spectroscopy (FTIR) (see INFRARED ABSORPTION SPECTROSCOPY (IR, FTIR, DRIFT, ATR)) to identify contamination in samples can save on pre-treatment, and avoid further alterations to the isotopic ratios caused by pre-treatment.

The establishment of isotope values can inform upon the intensity of agricultural labor, community relations, and the resilience of agriculture in the face of socioeconomic changes. The method has been used to inform upon long-term socioeconomic changes within a region, as well as agricultural strategies within a single settlement. The analysis of 124 crop samples from 13 Neolithic sites (5900–2400 BCE) across Europe showed that the mean site $\delta^{15}\text{N}$ values of cereals were between 3 and 6‰, elevated above the estimated $\delta^{15}\text{N}$ value of un-manured wild forage, providing the first widespread evidence for manuring practices in Neolithic Europe (Bogaard et al. 2013). The $\delta^{15}\text{N}$ and $\delta^{13}\text{C}$ values of 320 crop samples from five sites in northern Mesopotamia (6500–2000 BCE) indicate a shift towards extensive or lower-input farming practices in the fourth and third millennium BCE (Styring et al. 2017). The investigation of $\Delta^{13}\text{C}$ values in 275 cereal and pulse samples from nine Neolithic and Bronze Age sites in the eastern Mediterranean

and western Asia demonstrated locally variable irrigation practices, with evidence from one Neolithic and four Bronze Age sites across the region for the preferential cultivation of wheat (see WHEAT) in wetter conditions than barley (Wallace et al. 2015).

Crop isotope analysis has also been used to investigate chronological and spatial intra-site variations in cultivation practices. At the Neolithic lakeshore settlement of Hornstaad-Hörnle IA in southwest Germany, the $\delta^{15}\text{N}$ values of 197 samples of naked wheat, einkorn, and barley (see BARLEY, RYE, AND OATS) demonstrated that different households were pursuing different cultivation practices. At nearby Sipplingen, analysis of 45 samples of barley, einkorn, emmer, naked wheat, and pea indicated that cereals were cultivated with medium to high levels of manuring from ca. 4000 – 2800 BCE. At both sites, wheat and barley were grown under different conditions (Styring et al. 2016).

Further to the assessment of site-based irrigation practices, stable carbon isotopic ratios of archaeological plant remains have been used to assess the impact of long-term climatic variation on human society. An analysis of $\Delta^{13}\text{C}$ values from 1,037 crop samples from 33 sites across the Near East (10,000–500 BCE) identified a correlation between drought stress, here defined as $\Delta^{13}\text{C}$ values below 16‰, and periods of climatic instability. The study highlighted the significance of regional variance in agricultural strategies (Riehl et al. 2014). Analysis of wood and charcoal (see CHARCOAL AND WOOD ANALYSIS) through isotope dendroclimatology has demonstrated that analysis of stable carbon, oxygen, and hydrogen isotopes can provide information concerning multiple climatic variables, including temperature and water status (McCarroll and Loader 2004).

Reconstructions of paleodiet (see DIET AND NITROGEN ISOTOPES) have often presumed that human and animal plant diets would be isotopically comparable. While the potential variation in both the carbon and nitrogen isotopic ratio of plant material has long been recognized, archaeological plant remains have previously been considered too rare and/or too contaminated to be useful in paleodietary studies. However, the inclusion of crop isotopic ratios in a linear-mixing model of the paleodiet at

Neolithic Vaihingen, Germany enabled more accurate estimates of past protein consumption to be made. Utilizing the $\delta^{15}\text{N}$ values of 16 cereal and pulse samples, alongside isotopic values of humans and herbivores, the study inferred that the percentage of animal protein in human diets was substantially lower (29–46%) than that calculated using the typical estimates of plant $\delta^{15}\text{N}$ of 3‰ (Fraser et al. 2013). Moreover, $\delta^{13}\text{C}$ values of plant remains provide baseline values of C_3 and C_4 plants, allowing a more nuanced understanding of the consumption patterns of both animals and humans.

$\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ are often used in biochemistry to characterize the source of food items, and there is potential to apply this technique to archaeological plant remains. Wide variations in $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ from Bronze Age Syria have been used to argue for multiple sources for stored cereals from a single site (Fiorentino et al. 2015). The question remains whether variation between isotopic values of crops could be reliably identified as intersite variation, rather than variation driven by climatic and crop husbandry practices within one settlement. More promising is the investigation of the radioactive isotope of strontium ($^{87}\text{Sr}/^{86}\text{Sr}$), a technique widely applied to investigate human and animal mobility (see MOBILITY AND STRONTIUM ISOTOPES). Experimental studies have indicated potential for applying such methods to archaeological plant remains, but problems of contamination need to be resolved (Fiorentino et al. 2015).

Isotopic analysis of archaeological plant remains holds great potential to address major questions in archaeology and paleoclimatology, if isotopic analysis continues to be integrated alongside other lines of paleoethnobotanical and archaeological evidence. The application of the methodology to periods other than prehistory and beyond Europe and the Middle East will shed new light on human–plant–environment interactions. The construction of site-specific plant baselines will provide valuable data for paleodietary studies, enabling more accurate estimates of past dietary protein composition, but further work is still needed to resolve the trophic offsets between plants, animals, and humans. Several key areas require further experimental study to ensure the reliability of plant isotopic values. First, there needs to be an increased understanding of

the effect of the nitrogen cycle on the $\delta^{15}\text{N}$ ratios of archaeological plant remains, in particular the effects of salinity, microbial activity, and species variation (Szpak 2014). Second, there are issues to be resolved concerning the contamination of uncharred plant remains. Third, quality control methods for isotope measurements, which are available for isotopic analysis of collagen, need to be established. Currently, studies use %C, %N, and C:N ratios (Szpak 2014). Finally, isotopic data need to be accurately reported and made publicly available in open data archives, and analyzed using reproducible methods

Palynology

MICHAEL J. GRANT

University of Southampton, UK

The term palynology was established in 1944 via correspondence within the *Pollen Analysis Circular* where a suitable new name for the publication was discussed, as the term “pollen analysis” was deemed inadequate because it excluded the study of spores. After a series of suggestions, it was proposed that the term palynology would be most suitable, derived from the Greek word *palunō* meaning “strew, sprinkle” and the English suffix *-logy* (“the study of”) (Edwards and Pardoe 2017). Palynomorphs are defined by their ability to resist most forms of decay, other than oxidation, and therefore can survive the acid digestion techniques used in their extraction from sediments. This resistance is due to an extremely tough, inert organic material composed of sporopollenin, dinosporin, chitin, or pseudochitin. Palynomorphs derive from both aquatic and terrestrial environments and are present in geological samples dating back to the Precambrian. Palynology does not include organisms with siliceous or calcareous exoskeletons, although these may be informally classed as palynomorphs when parts of these skeletons, such as the organic foraminifera (see FORAMINIFERA) test linings, remain after acid digestion. Although the term palynology is synonymous with pollen analysis, and is often used interchangeably, it is used by paleopalynologists to embrace a wider range of microfossils, most of which are useful in archaeological studies. The most common microfossils regarded as palynomorphs are as follows:

- Acritarchs: an artificial group, whose name means “of uncertain origin,” of any small (typically 20–150 μm), organic-walled microfossil which cannot be assigned to a particular group but is believed to be related to unicellular marine algae; useful for defining Paleozoic biostratigraphy.
- Chitinozoa: large (50–2,000 μm) flask-shaped marine microfossils of an unknown animal; useful for defining Mid-Paleozoic biostratigraphy.
- Scolecodonts: jaws of polychaete annelid worms (typically 100–4,000 μm) composed of chitin and silica; common in Paleozoic deposits, though have limited biostratigraphic use.
- Dinoflagellates: unicellular microplankton (typically 5–2,000 μm), commonly autotrophs but heterotrophic forms also occur, found in a range of water conditions but most common in marine environments; important biostratigraphic and paleoenvironmental tools for the Mesozoic and Cenozoic.
- Pollen and spores: Pollen grains are the reproductive propagules containing the male gametophyte of gymnosperms and angiosperms. Spores commonly included within this category represent the sporophyte stage of lower flowering plants (Cryptogams) such as ferns (Pteridophyta) and mosses (Bryophyta). The earliest spores are recorded in the Late Silurian, with gymnosperms appearing at the end of the Devonian and angiosperms appearing in the Cretaceous, and therefore are useful in defining the biostratigraphy across this entire geological timescale up until the modern day. They typically measure 201–250 μm , though some Late Paleozoic megaspores can be up to 3,000 μm . Because of the ease with which they are transported by wind, water, and animal hosts, they can be found in almost all environments and sedimentary deposits and are the most studied of all palynomorphs.
- Non-pollen palynomorphs (NPP): a “catch-all” grouping used to describe a range of microfossils visible in pollen preparations not covered by the above categories. A large number have been identified as remains of diaspores, cyanobacteria, green algae, rhizopods, fungi, invertebrates, and chormophytes. Although NPP were observed in early palynological studies, the systematic study

DOI: 10.1002/9781119188230.saseas0438

of Quaternary NPP did not occur until the 1970s (see Miola 2012).

Samples for palynological studies can be obtained from sediments or organic material within stratified sequences (see CORING) or archaeological samples (see SAMPLING IN ENVIRONMENTAL STUDIES), or found directly adhering to archaeological material. Extraction techniques depend upon the type of palynomorph being studied, but will typically use acid digestion techniques, including hydrochloric acid (which removes carbonates) and hydrofluoric acid (which removes silicates; or equivalent heavy liquid separation technique), followed by oxidation, using either acetolysis or nitric acid, and then stained. Palynomorphs are identified using a compound microscope using transmitted light illumination, typically at $\times 100$, $\times 200$, and $\times 400$ magnification, or $\times 1,000$ oil immersion for detailed morphological identifications. Using taxonomic keys (e.g., Faegri, Kaland, and Krzywinski 1989), modern/fossil-type material, and high-resolution photographs, it is possible to use the distinct characteristics of each palynomorph to identify with a given type, family, genus, or even species. Palynomorphs, where modern equivalents exist, can be interpreted in two principal ways: first by comparing the fossil palynomorph assemblage to modern ones where the environmental conditions, such as vegetation composition or salinity, are known (modern analog method); and second, by using an indicator species, whose habitat is narrowly defined by ecological or climatic factors that have remained constant. Palynomorph preservation is strongly affected by various taphonomic (see TAPHONOMY) factors related to transport, deposition, diagenesis, and preservation potential, with poor preserving environments leading to either differential or total loss.

The earliest recorded descriptions of palynomorphs observed under a microscope were of pollen in the late seventeenth century, with dinoflagellates first described in 1753. During the nineteenth century, developments included the realization that pollen could be used for the systematic study of seed plants, and the first morphological descriptions and illustrations of palynomorphs were produced. Investigations of Paleozoic rocks revealed the presence of

fossil palynomorphs, notably dinoflagellates within Cretaceous chalk and pollen and spores within coal seams in England, Germany, and the USA. Beyond these early studies, there was limited development of the discipline until the pioneering work in Sweden by Lennart von Post and Gustaf Lagerheim looking at stratified pollen within Swedish peat deposits (see PEAT DEPOSITS). Von Post's 1916 address in Kristiania (now Oslo) is widely regarded as the birth of modern quantitative pollen analysis, leading to the introduction of many core aspects of palynology, including the pollen diagram, methodological advances in counting and dating, understanding the transport and preservation of pollen, and the phenomenon of regional parallelism in vegetation development and climatically mediated vegetational change (Edwards, Fyfe, and Jackson 2017). During the twentieth century, palynology had become fully embraced and evolved into a true interdisciplinary science, playing a key role in medical, geological, ecological, archaeological and forensic science, becoming an essential tool for the study of the past, the present, and the future of our planet.

The adoption of palynology into archaeology occurred early in the twentieth century when it was recognized that pollen could be used not only for paleoenvironmental reconstructions (see PALEOENVIRONMENTAL RECONSTRUCTION) but also to provide relative chronologies within a site or among a series of sites, based upon the concept of regional parallelisms and the construction of pollen zonation schemes aligned with the broad Late Glacial–Holocene climatic succession. It remained the main chronological tool until the invention and widespread adoption of radiocarbon dating from the 1940s onwards. Investigations of Pleistocene interglacial deposits revealed that pollen biostratigraphy could be used to correlate these deposits, withstanding testing by modern geochronological methods fairly well.

In 1937, Franz Firbas showed the possibilities of morphologically distinguishing between pollen from domesticated (see DOMESTICATION) and wild grasses. In 1941, Johannes Iversen was able to focus on specific archaeological questions using pollen, such as the start of the Neolithic period in Europe, based upon the decline in tree pollen and the appearance of

pollen of herbs and weeds typically associated with human occupation, including domesticated plants such as cereals. This introduced the concept that certain pollen types could provide “anthropogenic indicators,” along with demonstrating how humans had changed the equilibrium of the natural environment in the past. Rapid adoption of this approach occurred on all populated continents, and has been particularly effective in demonstrating the role that human impact has had in the formation of landscapes, including some long-presumed “pristine” regions. As the technique developed, notably through modern analog studies and modeling approaches to correct bias in pollen production and dispersal (see *VEGETATION MODELING USING POLLEN DATA*), quantified estimates of vegetation abundance strongly suggest that the influence of deforestation and agricultural activities on plant composition across northern Europe, from Neolithic times onwards, was substantially stronger than previously inferred.

Studies using pollen at the small scale also progressed throughout the twentieth century, notably those associated with archaeological sites, such as human coprolites and cadavers, buried soils, and pollen adhering to archaeological surfaces (e.g., ceramics or floors). These showed that pollen could be used to answer questions about human diet, use of plant resources, and the composition of on-site vegetation communities. It was also possible to highlight differences in the movement and deposition of pollen within urban environments compared to natural ecosystems (Greig 1982). Studies were undertaken into the detrimental impacts of humans upon their environment in the past, including soil erosion (see *EROSION*) and water pollution (see *WATER POLLUTION*), such as the introduction of non-indigenous dinoflagellate species into harbors and estuaries as a result of increased international trade.

While pollen has often been the main palynomorph used to address archaeological questions, there has been success in the use of NPP as both a complementary and stand-alone technique in environments where pollen and spores are not preserved. NPP can reveal additional details on a range of topics including human health from parasite ova and cysts (see *PARASITE OVA AND CYSTS*), livestock from

coprophilous fungi, ground destabilization and erosion from soil-inhabiting fungi, or burning from pyrophilous fungi.

Palynomorphs have also been particularly effective in identifying the provenance of rock materials, including stone and clay, found associated with archaeological sites. Using stratigraphic palynology, a branch of biostratigraphy, along with complementary techniques such as petrography, it is possible to use the palynomorph contents of materials to correlate them with stratigraphic sequences of known age and locations where these sequences are exposed (or have been quarried). Acritarchs, chitinozoas, and dinoflagellates have successfully linked artifacts constructed from Paleozoic stone or Mesozoic shale to their source locations, sometimes several hundred kilometers away. Similarly, when coal is encountered on sites as the fuel source, palynology can allow provenance to individual outcrops within coalfields. Palynology has also had some success in flint and chert sourcing studies, most notably by studying dinoflagellates contained within the raw material in order to resolve their geological age and provide a possible provenance (or at least eliminate some possible sources) to outcrops at a regional level (Harding, Trippier, and Steele 2004). Provenance studies can also be undertaken using palynology to ascertain the type of environment within which an artifact was created or stored prior to burial. Although palynomorphs are rarely preserved within materials that have been subject to high temperatures, such as fired ceramics, studies of poorly fired or half burnt potsherds have been shown to retain them, and can therefore be used to reconstruct the environmental setting where they were constructed.

The development of new techniques and applications within palynology, such as ancient DNA (see *PALEOETHNOBOTANY AND ANCIENT DNA ANALYSIS*) and advancing capacities for taxonomic precision, will allow the discipline to advance, as well as its inherent flexibility to play a major role in multidisciplinary studies and complement other techniques. Given the widespread adoption of palynology over the past century, generating vast amounts of data, the use of paleoinformatics offers an exciting opportunity to better understand past human impacts, including anthropogenic climate change.

Parasite Ova and Cysts

LIONELLO F. MORANDI

University of Reading, UK

Ova and cysts recovered from archaeological samples belong to a diverse group of intestinal parasites that can be divided into organisms visible by the naked eye, helminths, and microscopic taxa, protozoa. Cestoda and Trematoda (phylum Platyhelminthes, flatworms) are worth mentioning among the former, along with several species in the classes Secernentea and Enoplea, belonging to the phylum Nematoda (roundworms); protozoa are unicellular eukaryotic organisms, comprising amoeboid forms and other, often ciliate or flagellate species.

The interaction between humans and their parasites is a complex story that reaches back to the dawn of our species, when we shared the same microbiota with the ancestors of the other great apes (Moeller et al. 2016). The current ecology of intestinal parasites is particularly complex, as it results from an evolutionary history of a million years involving adaptation to several hosts in different environments. Contrary to popular opinion, the host/parasite relationship can also be a mutual one (McKenney et al. 2015). Parasites may have lived with humans much longer than previously thought (see HUMANITY AND ANIMALITY), and species infecting both people and other mammals may have developed before cohabitation with animals following domestication (see DOMESTICATION). This is indicated by phylogenetic studies (see DNA: MITOCHONDRIAL and GENOMICS: ANCIENT) supporting the presence of *Taenia saginata* (cattle tapeworm) in humans prior to cattle (see CATTLE) domestication, and is suggested by Mesolithic finds of possible eggs of *Trichuris trichiura* (although they might belong to *Trichuris suis*, the boar/pig-specific parasite).

Each species follows a specific life cycle, which cannot be completed without the appropriate host. Typically, a period of embryonation in a

suitable environment is followed by ingestion by one or more hosts, growth within their bodies, and discharge of the eggs with the stools. In the case of *T. trichiura* (human-specific whipworm), in order to survive, eggs need a permanence in a warm and humid environment for a period of about three weeks. However, after this period they become extremely resilient to environmental conditions. Hosts are infected through the accidental ingestion of contaminated soil particles. *Ascaris lumbricoides* (roundworm), the largest nematode in humans, follows a similar cycle but makes use of the bloodstream to carry the larvae to the lungs and eventually to the pharynx, where they are swallowed, prior to growth in the small intestine. An even more complex cycle is required for *Diphyllobothrium latum* (broad fish tapeworm) in order to infect humans. Embryos are ingested by freshwater crustaceans, which are eaten by small minnows, which are in turn predated by larger fish (see FISH). Humans contract the infection by eating raw or undercooked fish, and the tapeworm grows within the intestine, finally releasing eggs which are expelled with scats. If feces enter water, eggs become embryonated, leading to hatching of embryos, which are eaten by crustaceans, starting a new cycle. The *Dicrocoelium* genus (lancet liver fluke) involves two intermediate hosts (a land snail and an ant) to spread, and it is transmitted through the ingestion of an infected ant at the larval stage. Dicrocoeliasis often affects cattle, sheep, and goats (see SHEEP AND GOATS), and human infection is referred to as a case of pseudo-parasitosis, resulting from the consumption of infected animal liver. *Taenia* spp. (tapeworms) exploit humans as well as cattle and pigs (see PIGS) in order to complete their life cycle, and infection occurs through the ingestion of raw or undercooked meat.

The symptoms associated with helminth infection in humans are, in most cases, not very severe. Whipworms and roundworms may cause bloody diarrhea, vomiting, and iron-deficiency anemia (see ANEMIA). Diphyllobothriasis is associated with several symptoms, and because of the loss in vitamin B₁₂ the infected individual may develop

DOI: 10.1002/9781119188230.saseas0442

anemia. The symptoms associated with dicrocoeliasis in mammals are weight loss, anemia, and cirrhosis.

Parasite eggs and cysts can be recovered from excavated layers, lake deposits (see LAKE DEPOSITS), coprolites (see COPROLITES), and even directly from exceptionally preserved bodies, such as mummies. The eggs are normally identified in pollen slides by means of high-power optical microscopy (see OPTICAL MICROSCOPY). Specific procedures for the extraction of eggs have been developed, involving sieving through 160 and 20 μm meshes. More rarely, parasite eggs are recognized in thin sections (see MICRO-MORPHOLOGY), although in this case a precise identification is arduous and volumetric or weighted samples should also be prepared to allow accurate observation of the eggs' shape and surface.

Eggshells of the genera *Trichuris* and *Ascaris* (nematodes) are by far the most commonly observed by paleoparasitologists, because of both the existence of human-specific species and the resilience of the thick-walled eggs. Eggs of *Trichuris* vary between ca. 45 and 80 μm according to the species, and are characterized by an elongated barrel shape with slightly convex polar plugs at both ends. The wall is smooth and formed by a superimposition of three layers (a lipid, a chitinous, and a vitelline layer), with the core of the plugs being of unknown composition. Due to overlapping size, it is difficult to separate *T. trichiura* from *T. suis* (infecting suids). The genus *Capillaria* produces similar eggs that can be easily mistaken for *Trichuris*, but the former displays a typical reticulate surface ornamentation and a slightly asymmetrical position of the polar plugs. Fertile eggs of *Ascaris* range from ca. 45 to ca. 70 μm in length, the most apparent feature being a knobbed coat (albuminoid uterine layer) creating an anastomosed pattern. To an untrained eye, this coat, in addition to the ovoid shape of the egg, may easily resemble fern spores of *Polypodium* spp. The outer coat of *Ascaris* eggs is often partially lost, so that the smooth surface of the underlying vitelline layer is exposed. *Diphyllobothrium latum* produces large elliptic eggs (ca. 60–75 μm in length) showing a wide aperture on one side; similar but smaller and more slender eggs (ca. 34–45 μm) with an aperture (after the loss

of the operculum) belong to the genus *Dicrocoelium*. Eggs of *Taenia* (ca. 30–40 μm) display instead a spherical shape, the wall being thick and striated on the surface. Other helminths, less frequently recorded in archaeological samples, comprise eggs of various taxa such as *Ancylostoma*, *Enterobius*, *Fasciola*, *Schistosoma*, and *Strongyloides*.

Protozoan cysts, despite being common human parasites, are almost never recorded in archaeological samples because of preservation issues and the requirement for more sophisticated techniques. Light microscopy is not effective, and the immunological technique enzyme-linked immunosorbent assay (ELISA) is required (Gonçalves et al. 2005). The infection is detected by identifying specific antibodies related to antigens. Both sediments and coprolites can be successfully analyzed using this method.

It is often difficult to identify parasites to a species level, and many of the remains recovered in archaeological deposits could also derive from feces of wild and domestic animals. However, their value is not limited to the information they can provide on diseases that would not leave any trace on skeletal remains (see OSTEOLOGY). The study of these microfossils allows inferences on early population movements, as well as supplying information about living conditions in ancient settlements, providing data on dietary practices, use of the space, and social status.

One line of research involves the investigation of the origin and spread of human parasitic infections, using paleoparasitological evidence to shed light on large-scale movements of early human groups and the occupation of previously uninhabited continents. The arrival of hunter-gatherers in North America only through Beringia has been questioned, as eggs of *Trichuris* and *Ancylostoma*, requiring warm and moist soils, would not have survived in soil in the arid and cold permafrost. It is then difficult to explain the presence of these human-specific species in the stools of ancient populations in the Americas, and alternative colonization routes have been proposed (Araújo et al. 2008).

On archaeological sites, the informative potential of parasite eggs is manifold. They are useful indicators of dietary habits (e.g., consumption

of raw fish: Yeh et al. 2014) and poor hygiene during food preparation (e.g., soil contamination). Changes in subsistence strategies may be inferred by increases in certain parasitic species, such as in the case of fish tapeworm indicating fishing activities in Late Inca coprolites (Santoro, Vinton, and Reinhard 2003). In settlements, knowledge of the use and organization of space can be gained, as areas such as latrines and stables can be particularly rich in parasite remains (see MICROARCHAEOLOGY) (Langgut et al. 2016). Differences in social status, reflecting habits of different parts of the population, can also be detected. For example, in late medieval France, the abundance of *Taenia* eggs in cesspits adjacent to high-status mansions, relative to their absence in poor contexts, showed the consumption of raw meat as a specific practice within aristocratic families (Bouchet 1995). In graveyards, inhumations can be specifically sampled for paleoparasitological analysis in key areas, such as around the pelvis.

In paleoecological studies (see PALEOENVIRONMENTAL RECONSTRUCTION), parasite eggs of herbivores are useful indicators of local grazing pressure, as, unlike pollen and spores (see PALYNOLOGY), they are not transported over long distances by atmospheric agents, but deposited within dung pats and droppings.

In recent years, molecular paleoparasitology has become increasingly important, as it allows detection of infection even when eggs are not visible in routine microscopic analysis. Analysis of ancient DNA using the polymerase chain reaction method coupled with next generation sequencing (see DNA: NEXT GENERATION SEQUENCING) enables extremely accurate species-level identification in sediments and coprolites, opening new frontiers of paleoparasitological investigation (Côté et al. 2016).

Peat Deposits

SUZI RICHER

University of York, UK

Peat deposits occur when decomposing organic matter accumulates due to a reduction in microbial decay, usually through the process of waterlogging, which creates anerobic conditions in the organic layers below. Large landmasses in the northern hemisphere, such as those of North America, Europe, Russia, and Asia, coupled with climatic conditions that are mild/cold and humid, means that the northern hemisphere contains approximately 88–95 percent of the world's peat deposits. In spite of this dominance, significant peat deposits do exist in the southern hemisphere, particularly in tropical regions, in the form of mangroves and peat swamps.

Types of peat

Areas where peat deposits form in the northern hemisphere are given different names depending upon their characteristics:

- Bogs: are only fed by direct rainfall (ombrotrophic).
 - Raised bogs are isolated areas of peat; they usually form in the lowlands over depressions such as kettle holes, on floodplains, or in estuaries.
 - Blanket bogs form extensive areas in uplands.
- Fens: form where groundwater causes waterlogging, and they are characteristic of lowland areas.
- Mires: are active (or potentially active) systems where peat is currently being formed.
 - Blanket mires are where bogs and fen systems interconnect over large areas; these occur in Scandinavia.

The importance of peat deposits

Most peat deposits have accumulated over the Holocene, during the relatively mild and increasingly humid period since the last glaciation. The lengthy formation period undergone by deep peat deposits means that they have built-up a long-term record of proxy indicators for Holocene environmental, climatic, and anthropogenic change. Peat can preserve rare and significant organic archaeological remains, such as bog bodies, trackways, cloth, wooden artifacts, and occasionally food remains. While we can research both the natural development and human usage of peatlands in the past, the two are not separate, and arguably they are becoming increasingly linked, especially with the growing pressures facing peatlands.

The contemporary and future fate of peatlands has significance to archaeology and paleoecology, but also to the wider world. Over the centuries, as the peat has formed from rotting vegetation, so the carbon that was contained in the vegetation becomes locked away, making the peat into a large natural carbon storage unit. Approximately one-third of the world's soil carbon is contained in peat deposits. As peat deposits are excavated, drained, or burnt, this carbon is emitted into the atmosphere as the greenhouse gas (GHG) carbon dioxide, along with methane and nitrous oxide. With such a strong focus on reducing global emissions since the Paris Agreement in 2015, understanding, managing, and restoring peatlands is becoming an increasing global priority, not just for archaeology and wildlife, but also for the health of the planet.

How peatlands have been used in the past

While peat deposits are valued today as carbon sinks, and archives of valuable information about past environments, they were valued in ancient times for very different reasons. In upland and/or moorland contexts, peat often provided the only

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

© 2018 John Wiley & Sons, Inc. Published 2018 by John Wiley & Sons, Inc.

DOI: 10.1002/9781119188230.saseas0445

source of fuel for cooking and heating. Peat was cut into blocks, and then dried and stacked ready for use. Evidence of burnt peat has been found at a range of archaeological sites, including Neolithic and Bronze Age sites in Orkney, medieval sites in Greenland, and early medieval sites in Ireland.

The peatlands, or the wetlands that were present before the peat started to form, have been significant sites for votive deposition since late prehistoric times (approx. 800 BCE). These depositions have included human bodies, in the form of bog bodies, weapons, and food. The reasons put forward for deposition into peaty areas are many and varied, from them being boundary areas (between wet and dry, air and water, life and death), areas associated with bounty and fertility, or perceived as desolate and wild, to even just areas where accidental deaths and losses occurred and the burial environment led to their preservation. While we cannot fully arrive at an “answer” for how these boggy areas were perceived (see PERCEPTION AND EXPERIENCE), we can, as Giles (2009) points out, construct an interpretation (see INTERPRETATION) about peatlands and their usage by going through an “interpretive process of excavation, analysis and display.” The following section describes some of the methodologies needed for excavating and analyzing peat deposits; these are primarily rooted in an empirical (see EMPIRICISM) framework that is often more closely aligned with paleoecology than with archaeology. However, this does not mean that the study of peat deposits should always split along disciplinary lines; more that there is an increasing need to recognize that they will be studied, perceived, and understood by people with different epistemologies. This is especially the case as the threatened status of peatlands means that people from varying backgrounds (conservation, ecology, archaeology, paleoecology, history, art, literature, and general local interest) are increasingly working together.

How peat deposits are studied

Sampling

The sampling of peat deposits occurs in two ways, either through coring or from an exposed section

(see SAMPLING IN ENVIRONMENTAL STUDIES). Coring allows the extraction of a thin core (usually ca. 5–15 cm diameter) from above the deposit in question. The effect is much the same as coring an apple. The advantages of coring are that it does not rely on the presence of an excavated site; multiple cores can be extracted relatively quickly; and a greater depth can be reached compared to excavation alone, including going beyond the water table. Sampling from a section usually from within an excavated archaeological trench or from a section exposed as a result of erosion, such as a stream-cut or cliff, is carried out using bespoke monolith tins or guttering. The benefits of taking monoliths from sections are that the analyst has the advantage of seeing the stratigraphic context and can choose the best placement of the monolith tins based on factors such as proximity to other archaeological material and areas of potential disturbance. Second, larger subsamples can be obtained for analyses.

Characterizing the deposit

Peats are firstly characterized and described, usually at the point of sampling, in relation to their degree of humification (the breakdown of the organic material). The main system of field description employed in the northern hemisphere is the Troels-Smith (1955) scheme; initially developed in the 1950s, this system describes the composition, degree of humification, and the physical properties of the deposit (Rabby 2013). These initial descriptions are often tested when the samples arrive in the laboratory (see ‘Geochemistry’ below).

Macroremains

Common macroremains that can be found in peat deposits include:

- wood
- macroscopic plant remains (see PALEOETHNOBOTANY)
- insects (see ARCHAEOENTOMOLOGY)
- molluscs (see LAND AND FRESHWATER MOLLUSCS)
- human remains, including soft tissue such as skin, as well as bone, hair, and finger nails

- vertebrate remains (see ZOOARCHAEOLOGY)
- other archaeological remains such as flint, pottery, and metal work, fibers (see FIBERS), and residues (see ORGANIC RESIDUE ANALYSIS).

Some of archaeology's most enigmatic sites and finds have been from peat deposits, primarily due to their ability to preserve organic remains that are often lost on dryland sites. These finds have included those from 2000 BCE–120 CE (Bronze Age–Roman period) bog bodies from all over northern Europe, such as Tollund Man (Denmark), Kayhausen Boy (Germany), Cashel Man (Ireland), Weerdinge Men (The Netherlands), and Lindow Man (UK)—all of which had substantial or fatal wounds.

On a landscape scale, the Somerset Levels, UK, have seen prolonged and extensive work on both the archaeological and paleoecological micro- and macroremains contained within the peat deposits. These have included the excavation and analyses of trackways and lake villages. More recently, the condition and hydrology of the peat itself has been assessed for the future management of these sites (Brunning 2013).

Microremains

The most frequently analyzed microremains—and probably the most familiar to archaeologists—are pollen grains (see PALYNOLOGY), although a range of analyses on other microparticles and -organisms can also be highly informative about the past environment and its usage. These include:

- Nonpollen palynomorphs (NPPs) such as fungal spores and parasite ova (see PARASITE OVA AND CYSTS). Frequently found on pollen slides, these microfossils can provide other proxy evidence alongside pollen, which is often related to the local environment, and particularly to hydrological conditions in peatland contexts.
- Testate amoebae (see TESTATE AMOEBEA ANALYSIS): These single-celled organisms survive well in peat deposits and can be used as indicators of hydrological change in peat bogs over time. They respond to changes in

moisture on the surface of the peat, allowing a transfer function (an equation) to be applied, which allows past changes in the water table to be inferred.

- Diatoms (see DIATOMS) that are present in all aquatic environments can be used to reconstruct hydrological changes in the peat.
- Charcoal: Microcharcoal is often encountered on pollen slides, and while the cause of the fire (human or natural) often remains obscure, its presence can inform us about past landscape change within the local area of the site, and up to ca. 96 km (60 miles) away.
- Spheroidal carbonaceous particles (SPCs): These small particles, ca. 50 μm in diameter, are the product of the incomplete burning of fossil fuels at high temperatures that are required for industry (see AIR POLLUTION). They provide an indication of past industrial activity and, as such, can be used as chronological markers within a peat sequence for the historic period (see below).

Geochemical analyses

The chemical properties of the peat deposit itself are important for understanding the environmental and climatic conditions under which the peat formed, activities occurring around the sites, taphonomic processes that may have affected (and continue to affect) macro- and microfossils within the peat, and potentially how the peat may respond in the future to changing conditions (see SOIL CHEMISTRY IN ARCHAEOLOGY). Peat is primarily composed of organic material, but it also consists of a smaller inorganic fraction. This inorganic fraction provides information about conditions or activities that usually occurred off-site, such as erosion (natural or human-induced), industry, fire, and wind-blown dust movement. The following methods can be used to study the geochemistry of peat deposits:

- Organic geochemistry: The amount, or degree, of humification of the peat is an indicator of how much vegetal decomposition has occurred. Very simply, in dry or warm periods, peat becomes more humified (dark and finer) as decomposition occurs; however,

this should be tested against other proxies for moisture as well. Given that peat is composed of decaying vegetation, all peat is humified to some extent, but this will vary depending on the type of peat, the climatic and local conditions, time, and depth. The degree of humification was traditionally established by visual inspection (see “Characterizing the deposit”) but is now increasingly undertaken by pyrolysis gas chromatography and Fourier transform infrared (FTIR) spectroscopy (see INFRARED ABSORPTION SPECTROSCOPY (IR, FTIR, DRIFT, ATR)). Bulk analysis of the carbon–nitrogen ratio can also indicate the degree of decomposition.

- Inorganic geochemistry: Elemental and isotopic analyses are increasingly undertaken on peat deposits. Potentially the most useful analyses undertaken from an archaeological perspective are those relating to heavy metal pollution, for instance lead (Pb) pollution from mining activities. Analysis of the inorganic chemical composition of peat is increasingly undertaken through X-ray fluorescence (see X-RAY FLUORESCENCE SPECTROMETRY (XRF)). Elemental analysis has usually been carried out by removing organic matter and water content from samples before analysis, but, more recently, experimentation with scanning complete cores has been carried out.

A case study that combines microfossil and geochemical analyses from a peat deposit in central-western Spain can be found in the work of Silva-Sánchez et al. (2016). Here, pollen, NPP, and charcoal analyses were combined with organic and inorganic geochemical analyses for a sequence dating to the Little Ice Age (sixteenth to nineteenth centuries) in order to examine the effects of climate change (temperature and moisture) on carbon accumulation, and the effect of land use change on erosion and mineral influx.

Chronologies

Due to the more-or-less continuous accumulation of organic matter in most peat deposits, they are ideal for the construction of age-depth models (models that allow us to interpolate

between known ages). The recent increase in the usage of programs such as OxCal and Bacon (for references see Piotrowska, Blaauw, and Mauquoy 2011) for the creation of Bayesian age-depth models has allowed a move away from the previously favored (and highly inaccurate) method of linear interpolation, which involved purely drawing a line between dots. Instead, Bayesian age-depth models are created that take into account the errors associated with each individual measurement, in conjunction with all relevant prior knowledge about the site/sequence in question (e.g., stratigraphic changes, distance between the radiocarbon determination). Advantages, they also permit statistical estimations to be made for undated points on the age-depth curve between measurements; and they can provide a more precise estimate for the original calibrated date. Bayesian age-depth models can be constructed with dates obtained from various sources; those that can be employed on peat deposits include:

- Radiocarbon dating: When choosing samples from a peat sequence, it is best that short-lived plants are chosen, particularly those growing on the site, such as *Sphagnum*. For highly humified peat, it is not always possible to select an in-situ plant macrofossil, in which case either bulk samples or fractions of the samples can be dated. Wherever possible it is best to obtain dates on both the humic (acids from the decomposing vegetal matter) and humin (the organic detritus) fractions of the peat; ideally there will be consistency between these measurements, but where they differ, the humin fraction is generally regarded to be the best approximation, due to the fact it is less mobile through the profile than the humic acids (Piotrowska et al. 2011). However, this decision can only be made on a site-by-site basis.
- Spheroidal carbonaceous particles (SPCs): Within the UK and Ireland, a database (CARBYDAT) of SPCs has been produced to allow the regional dating of peat and lake sediments from the 1800s (Rose and Appleby 2005).
- Tephrochronology (see TEPHRA AND VOLCANIC ASH ANALYSIS).
- Dendrochronology: This technique is especially useful where archaeological material,

such as trackways, structures, and wooden artifacts, survive within the peat. The first pre-historic chronologies based on oak tree rings in the UK were outlined in the mid-1980s and used to provide a date of 3807/6 cal BCE for the Sweet Track, a Neolithic trackway running ca. 2,000 m (6,600 ft) across the Somerset Levels, UK (Hillam et al. 1990) that was subsequently preserved in the peat that consumed it.

- ²¹⁰Pb dating: Naturally radioactive lead-210 occurs in the atmosphere and eventually settles into soils and sediments. This radiometric dating technique is only suitable for dating deposits that have accumulated over the last ca. 100 years due to its relatively short half-life (22.3 years).

Threats to peat deposits and the archaeology contained within them

Today, the largest threats to peat deposits in the northern hemisphere are their continued commercial extraction for (1) use as a fuel, especially for heating and power generation in Finland, Ireland, and Sweden; and (2) use in horticulture and agriculture, for example for compost or soil improvement. Another significant problem facing peat deposits, especially in lowland areas (and in the southern hemisphere), is deforestation and drainage of peatlands for cultivation; this effectively lowers the water table, which not only allows the release of stored carbon, but also encourages the degradation of any organic material contained within the peat. Experiments on the effects of a changing and fluctuating water table in peat deposits on archaeological material at the Mesolithic site of Star Carr, North Yorkshire, UK, have shown that water-management practices in peatlands can severely affect the preservation of organic remains; for example, both bone and wood were found to have deteriorated irreparably within a shockingly short period of time: just one year (High et al. 2016). This in turn has implications for the in-situ preservation of any archaeological sites and artifacts contained within peat deposits and for the preservation of micro- and macro-environmental remains.

Phytolith Analysis

LISA-MARIE SHILLITO

Newcastle University, UK

The term phytolith refers to biomineral deposits that form within and between the cells of plants. Most often phytolith refers to opaline silica ($\text{SiO}_2 \cdot n\text{H}_2\text{O}$) deposits which form a three-dimensional “cast” of the cell morphology, but is sometimes also used for other plant mineral deposits such as calcium oxalate ($\text{CaC}_2\text{O}_4 \cdot \text{H}_2\text{O}$). Calcium oxalate deposits form crystals within different parts of the plant rather than forming cell casts. Forms include granular or rosette-shaped crystals called druses, needle-shaped crystals called raphides, various prismatic shapes, rectangular styloids, and block-shaped aggregates called “crystal sand.” Calcium oxalate crystals can be a major component of plant ash; however, they are removed through standard phytolith processing methods and are not often studied in archaeological samples. There are also problems in distinguishing these from naturally occurring calcite crystals, which have similar morphologies and optical characteristics.

Silica is present in the soil from weathering of silicate minerals such as clay and feldspar, and is absorbed by plants in solution in the form of silicic acid. The silica is transported throughout the plant and deposited in areas with high evapotranspiration, most commonly in the epidermal cells of leaves, stems, and bracts. Short cells (such as rondels and cork cells) within the epidermis are the first to become silicified and in some cases may be the only cells that silicify. Other types of cells such as hair cells and stomata guard cells can also become silicified. Certain types of plants accumulate silica in greater quantities than others. Monocotyledonous plants, particularly Poaceae (grasses, including cereals) and Cyperaceae (sedges), and Equisetaceae (horsetails) have high rates of silica deposition, which can be up to 4 percent by weight. Intermediate deposition between 2 and 4 percent is seen, for

example, in Cucurbitales (squashes) and Urticales (nettles).

Factors influencing silica deposition are complex, and include soil pH, availability of water and nutrients during plant growth, and climatic conditions. The mechanisms of deposition are largely determined genetically and some plants actively accumulate silica regardless of external factors. This is thought to be related to pest resistance. Environmental factors, however, have a significant influence, with high availability of silica and water flow favoring phytolith formation. For this reason, phytoliths are produced in much greater quantities in environments with high evapotranspiration rates. In these environments whole sections of plant tissue can become silicified, forming very large phytoliths where hundreds of individual cells are conjoined. These are often referred to as “silica skeletons.” In more temperate environments the degree of silica deposition is much lower, leading to lower numbers of phytoliths which are less well formed, making research in such regions more challenging. In these environments only the individual cells are recovered.

The history of phytolith analysis can be traced as far back as the 1800s, when they were first reported by the German scholar Struve, who wrote a dissertation on the subject in 1835, and “phytolitharia” were identified in dust collected by Darwin on the *Beagle* (Darwin 1846). In the later nineteenth century and early twentieth century, phytoliths were studied mainly by botanists, with the earliest archaeological studies conducted in the 1950s and 1960s. A turning point came with the publications of Rovner (1971) and Piperno (1988) that helped establish phytolith analysis as an important tool within archaeology and paleoecology. The technique is now well established, though not routinely applied.

It is a particularly useful technique as phytoliths survive when other types of plant remains do not, as they do not have to be burnt or waterlogged to preserve in the archaeological record. Phytoliths survive in most environments, being subject to erosion in conditions of extreme high

pH, and even in these circumstances they may survive in a weathered form. Phytoliths have been utilized for a wide range of research areas, including studies of diet, agriculture, fuel use, examination of architectural and craft activities, and detection of activity areas. Compared to other microfossil analyses such as palynology (see PALYNOLOGY), our understanding of the formation processes (see FORMATION PROCESSES) and taphonomy (see TAPHONOMY) of phytolith assemblages is relatively poor. Unlike pollen, phytoliths are usually assumed to occur “in situ,” with limited transportation by wind and water, and thus are assumed to give a highly localized signal of plant presence. However, experimental work has recently questioned this assumption, indicating that phytoliths can be moved through other mechanisms and do not necessarily represent in-situ deposits. Sampling strategies need to take into account these issues, and will depend to an extent on the questions being asked.

Phytoliths can be extracted from bulk sediments, specific microarchaeological layers, and “sealed” contexts such as within dental calculus and burnt food residues (see FOOD RESIDUE ANALYSIS) on pottery. Understanding the precise depositional context is important for interpreting phytolith assemblages. Combined phytolith and microstratigraphic analyses have demonstrated that similar phytolith assemblages can occur in deposits that come from a diverse range of activities (Shillito 2011). Samples collected from artifacts are less problematic as it is easier to associate the microfossils with the specific deposit/activity. Other approaches include horizontal or systematic sampling across a defined surface at regular intervals, in order to map densities and identify potential activity areas. As with other techniques, such as geochemistry, that aim to map concentration and variation across a surface, this approach can be problematic as it is not always easy to identify the origin of deposits, and several layers/activities can be mixed. Sampling vertically through soils is also an option, to examine change in the phytolith assemblage over time, though movement of phytoliths throughout the soil makes this problematic.

Studies combining phytolith analysis with thin section micromorphology (see MICROMORPHOLOGY) have become increasingly common

to try to identify and account for these formation processes (Albert et al. 2008; Vrydaghs, Ball, and Devos 2016; Sulas and Madella 2012). This approach can also identify whether movement is occurring in sediments, and by which mechanisms, for example, bioturbation or percolation. By microsampling thin section blocks, a direct link can be made between the phytolith assemblage and the precise depositional context, and can help identify whether there is a single deposit or cumulative palimpsest.

A major area of phytolith research is the identification of domesticates, crop processing, and agricultural practices. Research on modern plants has shown statistically significant differences in the average shape and size of phytoliths in domestic compared to wild varieties of plants, including maize, rice, and wheat. Caution needs to be applied in archaeological studies, where small numbers of phytoliths may not provide a sample set that is large enough to unequivocally distinguish between morphologically wild or domestic forms (Shillito 2013). A further strength of phytoliths compared to other botanical remains is the ability to identify different parts of the plant, for example leaves and stems versus chaff and husks, which in turn enables agricultural activities such as crop processing to be inferred. It is also possible to identify whether plants have been irrigated (or, at least, the extent of water availability), on the basis of tissue size and the ratio of short cells to long cells.

Phytoliths from ash deposits can be used to identify both wood and nonwood components of fuel. Ash that results from the burning of wood is calcite rich with amorphous silica phytoliths and oxalate pseudomorphs, whereas the burning of reeds and grasses produces silica-rich ash with morphologically distinct phytoliths. The presence of phytoliths from reeds and sedges can also provide information on the exploitation of wetland resources for activities including matting and roofing.

The ease with which specific genera or species can be identified varies considerably. As they are exact replicas of plant cells, an understanding of plant cell morphology can help the process. The large articulated tissues that are seen in some parts of the world are relatively easy to identify taxonomically through comparison with reference collections. In many cases such tissues

are not formed or are not preserved, and we have only individual or small groups of cells. In this case only a general grouping can be made, and a typological approach can be used to try to link a phytolith to a particular plant part or taxa. The International Code for Phytolith Nomenclature (ICPN) was proposed (Madella, Alexandre, and Ball 2005) as a means of standardizing typological descriptions; however, there is still considerable variability in the application of the ICPN, which makes comparative studies difficult.

A further problem in phytolith analysis is the huge degree of variability in phytolith morphology, and the fact that similar morphologies can be found in different taxa, which may or may not be related. It is important therefore to be realistic about the level of identification that can be achieved in different circumstances, and the interpretations we can make. It is not always necessary to be able to assign a specific genera or species; for example, the morphology of short cells can be used to identify whether an assemblage is dominated by C3 or C4 plants, which in turn can help with paleoenvironmental reconstructions.

Geographically, phytolith analysis has seen greatest applications in the Americas, South West Asia, and East Asia, with an increasing number of studies being conducted in temperate Europe as researchers work to address the limitations of the technique in these environments. Current emphasis in archaeological contexts has been on understanding taphonomic processes and depositional pathways, where ethnoarchaeological and experimental studies are providing important insights. The integration of phytoliths with other data as part of multiproxy approaches, already standard within paleoenvironmental research, is also becoming increasingly common in archaeology.

FURTHER READINGS

Pigs

UMBERTO ALBARELLA

University of Sheffield, UK

The pig (*Sus domesticus*) is one of the most important domestic animals, contributing substantially to human diets, cultures, lifestyles, and beliefs. Along with cattle (see CATTLE), sheep, and goats (see SHEEP AND GOATS), it was one of the earliest animals to be domesticated. Only dogs were definitely domesticated earlier. As the domestication of the pig was part of a process that led to the “farming revolution” and the advent of the Neolithic, it is no exaggeration to suggest that it transformed human life on earth as no other innovation.

The wild ancestor of the domestic pig is the wild boar (*Sus scrofa*), whose original distribution includes most of Europe, Asia, and North Africa. The wild boar is a typical woodland species, though its habitat can be diverse and, in its range, the species is only absent from the driest and coldest environments. The wild boar was an important game species for many Paleolithic and Mesolithic populations, as well as for later prehistoric and historic societies. In classical and medieval times the hunting of wild boar was regarded as especially dangerous and therefore only suited to the bravest hunters. Classical mythology contains many references to wild boar. One of Heracles’ labors consisted of the chasing of a giant wild boar; it is through a scar ensuing from a wild boar hunt that Odysseus is recognized on his return to Ithaca; and Mycenaean noble warriors wore wild boar tusk helmets, as described in Homer and Mycenaean iconography, and demonstrated by archaeological evidence.

Due to the wide geographic distribution of its wild ancestor, potentially the pig could have been domesticated in many different areas. There is, however, some consensus that the initial domestication occurred in the Near East, with Turkish sites such as Cayönü and Hallan Çemi providing some of the earliest evidence (ca. tenth to seventh millennium BCE) (Rosenberg et al. 1998; Ervynck

et al. 2002). Genetic research, however, has led to the suggestion that the domestic pig is the product of multiple domestication events, occurring in different parts of the world. Independent domestication in the Far East is nowadays regarded as highly probable. In Europe the integration of zooarchaeological and genetic evidence provides a pattern that is compatible with a blend of introduced and local domestication (Albarella et al. 2006). Southeast Asia hosts several other wild *Sus* species, and the possibility that at least one of these also could have been domesticated has been raised (Groves 1981), though current scholarship has questioned this.

After its initial domestication(s) pigs became widespread in Eurasia and Africa, but they did not reach the Americas until the arrival of the Europeans in the fifteenth century. They probably reached Oceania from South-East Asia, but the form and timing of this event is still debated.

One of the problems in identifying the emergence of domestic pigs concerns the difficulty in separating the archaeological remains of wild boar and domestic pigs. This is an issue that affects all periods, but particularly the earliest stages of domestication, when wild boar and domestic pigs were morphologically still very similar. It has been suggested that morphological changes—at least those that can be perceived archaeologically—only emerged well after the earliest onset of the domestication process. Of these changes the most obvious is a reduction in body size, but a relative shortening of the snout and a decrease in sexual dimorphism have also been observed. To detect domestic pigs in the archaeological record it is important to consider, in addition to morphometry, multiple lines of evidence, including age profiles, sex ratios, and genetics. Isotopes can inform us on feeding regimes, which may have differed between the two forms. In the Mediterranean, Southeast Asia, and the Far East considerations have also been based on the occurrence of pigs on islands previously devoid of wild boar. Logically this should suggest that the pigs were imported there by people. However, wild boars are strong swimmers

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

© 2018 John Wiley & Sons, Inc. Published 2018 by John Wiley & Sons, Inc.

DOI: 10.1002/9781119188230.saseas0459

and, in some cases, they may have arrived on these islands independently.

Our ability to separate wild boar and domestic pigs hinges on the degree of physical—and consequently genetic—separation between the two forms. The extent to which such separation will occur is dependent on the adopted husbandry strategies. In the past, free-range pig herding was common, and this would generate domestic pigs with morphological characteristics that are not very different from those of the wild boar. These pigs would be subjected to many of the same adaptive pressures that characterize the wild boar (e.g., the retention of long snouts to allow digging for products such as roots and tubers). Additionally, free-range pigs could readily interbreed with wild boar, therefore generating a genetic and morphological continuity between the two populations. Free-range pig-keeping must have been the norm in prehistoric times—it has the advantage of low labor requirements as pigs can thrive even without human support. Yet, changes identified in several geographic areas suggest that between the Early and Late Neolithic the degree of separation between wild and domestic forms increased, probably as a consequence of greater human control, including enclosure. This trend continues in the metal ages, at least in Europe. The drift towards size reduction, which began with the initial domestication, largely continues until the end of the prehistoric period. The smallest domestic pigs are found in the Bronze and Iron Ages, before the “improvements” that characterize the historical periods.

The Romans made deliberate attempts to improve farm animals, and pigs were no exception. Several breeds are known from Roman written sources, and archaeologically both large and small morphotypes have been recognized in Italy. The small breeds remained the most popular, perhaps because they were more mobile and easier to drive towards urban centers. The larger pigs were probably mainly used for sacrificial purposes as the iconography of the time suggests (MacKinnon 2001). Although pork was the preferred meat in Roman Italy, this was not the case in other areas of the Roman Empire, where beef and mutton were more commonly consumed.

In the Middle Ages pigs could be kept enclosed or free range according to the husbandry culture of the time and area. The taxation system known as “pannage,” allowing for the pasturing of free-range pigs in the forest, is particularly well known in England, but similar practices occurred elsewhere. In later medieval times and in the modern period, pigs could also be found roaming town streets (often causing a nuisance). The single sty-pig, generally confined to the backyard of a house, is, however, an almost exclusive modern phenomenon. It is this practice that led to the creation of the fat, large, pink, and fairly hairless pig that typically characterizes the contemporary image we have of the animal.

Unlike other farm animals, pigs do not provide secondary products, such as wool or milk, and are generally exclusively raised as food providers. Even the skin is most typically used as food, though it could occasionally serve other purposes, such as in footwear. An interesting exception is represented by black Korean pigs, which used to have their sties associated with human toilets. They fed (partly) on human excrements, therefore also fulfilling an important cleansing role. Such practice also occurred in China during the Han dynasty (300 BCE to 300 CE), as attested by numerous figurines, typically funerary models, recovered from archaeological sites.

The sty-pig has in the contemporary world become confined to traditional rural areas, while the most common form of pig breeding is through intensive factory farms, raising both environmental and animal welfare concerns.

Free-range pigs can, however, still be found in many parts of the world. The pigs of Papua New Guinea have famously been discussed in the ethnographic literature, but free-range pigs are also known from other areas, such as South Asia, the Caucasus, the Balkans, Iberia, and several Mediterranean islands. They tend to provide products of much greater quality than the intensively reared pigs, and have a much smaller environmental impact. Because of their lifestyle these pigs are slim, often small, and highly mobile (Figure 1). In Sardinia, pig transhumance was practiced until a few decades ago and the practice is also known, through literary sources, in medieval France and Spain (Albarella, Manconi, and Trentacoste 2011). The

possibility of long-distance pig herding in prehistory has been raised on the basis of isotopic evidence (see ZOOARCHAEOLOGY AND STABLE ISOTOPES).

Pork is and has been consumed all over the world, and it has a particular prominence in East and Southeast Asia. It is, however, *not* eaten in Islamic and Judaic societies. This food avoidance is long-standing and has been documented archaeologically. Though some archaeological sites associated with Muslim and Jewish cultures are indeed entirely devoid of pig bones, others are not, which suggests that this food taboo was not always strictly followed.

Pig meat was not only a source of nourishment; in many societies it also played an important social and ritual role. Pigs are the quintessential feasting animals as they have a high reproductive rate. They can be sacrificed in large numbers without jeopardizing the herd. Feasting events heavily based on pork consumption have been recognized at several prehistoric and historic archaeological sites.

Pigs have also been associated with rites of fertility. Their fecundity makes them ideal for this role. Piglet bones are frequently found in ritual contexts, often burnt. The practice is well known—through iconography, history, and archaeology—for the Romano-Greek world as well as in prehistoric caves. The most famous use of pigs in classical rituals is through their association with the myth of Demeter and Persephone, attested both historically and archaeologically.

Pigs have enriched life on the planet and have accompanied human societies in their journey through more than 10,000 years of history. They have supplied proteins but also company and inspiration. They represent a regular feature in many works of art, poetry, and literature. People should not forget the debt of gratitude they owe to pigs and that the mistreatment of these animals is not only ethically despicable but also an insult to the rich history that characterizes our relationships with these remarkable animals.

Pollution and Heritage Conservation

CECILY M. GRZYWACZ

Retired Cultural Heritage Scientist, USA

For as long as humans have been creating cultural heritage there has been a risk of damage from pollution. In our quest to preserve heritage, we must recognize and manage the risks to artifacts that we want to protect. The effects of pollution are as varied as types of cultural heritage. Sources and types of pollutants are numerous. In order to identify the threat of pollution to heritage it is important to understand the material composition of that heritage.

A pollutant is a substance that has a detrimental effect on the environment or on something of value, and is present in the atmosphere in amounts greater than the natural concentrations, primarily due to human activity. Heritage can be threatened by outdoor pollutants, such as gases and particles from vehicle exhaust. Outdoor pollutants can make their way into buildings and can affect heritage inside museums. Artifacts indoors are also threatened by pollutants generated from sources within, such as fumes from cleaning products.

The types of pollution that can threaten heritage depend on the activities within the meteorological range of the site. Major outdoor sources of pollution include natural sources, agriculture, atmospheric reactions, industrial processes, and vehicles. The geography of the site and the weather patterns can determine the pollution matrix at a heritage location. Indoor air quality can be affected by outdoor air quality that infiltrates the building. Once inside, the indoor air quality is a function of the types of heating, ventilation, and air conditioning systems, processes and activities within the building, and materials used within the space. Major indoor sources are combustion (cooking, smoking, heating), materials off-gassing, gas-phase reactions, cleaning solutions, and human activity. A

pollutant can be a gas, liquid, or solid. Pollution and heritage conservation is usually concerned with airborne particles and gases.

Particles can be composed of carbon, alkaline materials, silicas, salts, metals, and so on. They can be visually intrusive, abrasive, or sites for chemical reactions. Particles are recorded as the number or weight of particles at a specific size in micrometers (μm). Typical sizes reported are PM10 or 10 μm , PM2.5 or 2.5 μm , and PM1 at 1 μm . Additionally, we now must consider the adverse effects of nanoparticles, which have increased in number with combustion engine improvements. These smaller particles are difficult to keep out of environments.

Gaseous pollutants can be generated indoors and outdoors. Typical outdoor pollutants are sulfur dioxide (SO_2), nitrogen oxides (NO , NO_2), reduced sulfur compounds such as hydrogen sulfide (H_2S), carbonyl sulfide (COS) and carbon disulfide (CS_2), ammonia (NH_3), and peroxides like ozone (O_3). There are also indoor sources of these chemicals (Grzywacz 2006). Indoor pollutant compounds number in the hundreds. Several are recognized as threats to heritage: organic carbonyl pollutants, specifically formaldehyde, formic acid, acetic acid, reduced sulfides, ozone, amines (R-NH_2), and volatile organic compounds (VOCs). The small-molecule organic carbonyl pollutants are known to be a risk because analysis of corrosion products on artifacts has identified acetates and formates.

Gases are measured volumetrically in parts per billion (ppb) or weight per volume of air, micrograms per cubic meter ($\mu\text{g}/\text{m}^3$). The concentrations that pose a risk to heritage are usually in the ppb or $\mu\text{g}/\text{m}^3$ range, whereas human health concerns are usually a thousand times more concentrated at parts per million (ppm or mg/m^3). These are very small levels. One ppb is equivalent to one yellow ball in a line of one billion white ping-pong balls that it would take to wrap around the equator of the earth.

Which pollutant/contaminant is a risk to the preservation of heritage resources is dependent upon the materials of the artifact. To understand the risks, the conservator must know the

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0468

materials. Grzywacz (2006) recommends target levels for gaseous pollutants in museum environments. Current concentration limits are based on limited empirical evidence of visible damage and known concentrations. Health guidelines are used as starting points, because regulations are available. Natural background levels and urban levels are used as a reference for what concentrations are achievable.

Damage from pollution is a function of the sensitivity of the material(s), the exposure time, and pollutant concentration. A large amount of a pollutant in an environment with a susceptible material or artifact will likely result in visible damage in a short time. A low concentration can also be a risk over a long period of time. Hatchfield (2002) and Tétreault (2003) recommend strategies to mitigate pollution for heritage conservation. *ASHRAE Handbook–HVAC Applications*, chapter on “Museums, Galleries, Archives and Libraries,” is reviewed every four years and includes a section on airborne pollutants, target levels, and risk to heritage.

Potatoes

J. FRANCISCO MORALES-GARZON

International Center for Tropical Agriculture, USA

Paleoethnobotanists study plant macro- and microremains from archaeological sites in order to understand the subsistence strategies of ancient societies, and the environmental conditions prevalent at that time. Paleoethnobotany (see PALEOETHNOBOTANY) also guides botanists and plant taxonomists in their search for the centers of origin and domestication of useful plant species. These two objectives are closely related due to the evolution of plant species over time. Basically, most of the cultivated plants currently known are not the same plants that *Homo sapiens* encountered in the territories that they colonized during the Late Pleistocene or Early Holocene epochs. Most of the existing cultivated plant species are the product of natural or controlled hybridization of genetically compatible wild species, followed by natural (environmental) or human-mediated selection (see DOMESTICATION).

The potato that became the world's third-largest food crop is genetically different from the original potato that once emerged in the center of origin of this species (*Solanum tuberosum*) in southern Peru, South America. In fact, *S. tuberosum* was unknown to the Old World and even outside South America in ancient times. Yet, many wild, tuber-bearing potato species existed from central Chile and Argentina to the southwestern United States before the arrival of *H. sapiens* in the Americas. Interestingly, Mexico is considered one of the two centers of genetic diversity of wild potatoes, even though potatoes were never cultivated or consumed in Mexico or Mesoamerica in pre-Hispanic times. The point is that the potato has an extremely large secondary gene pool of different but related species, mainly in its primary center of diversity in the Andean region of South America. Following the latest taxonomic proposal, 110 tuber-bearing potato species are listed in the genus *Solanum* section *Petota*; and three nontuber-bearing potato species are

assigned to the section *Etuberosum*. This extreme genetic diversity and, yet, morphological similarity of many wild and cultivated potatoes has been the nemesis of even the most experienced potato taxonomists in the world. Considering the difficulties faced by expert taxonomists having access to extant potato germplasm collections, well-maintained plant herbaria, and molecular tools to study plant systematics, it is possible to understand the challenges encountered by archaeologists trying to identify ancient remains of unknown potato species.

The site of "Monte Verde" in southern Chile, South America, is probably the most famous archaeological landmark in the Americas. This site pre-dates by over 1,000 years the equally archetypal site of "Clovis" (dated to about 13,000 BP) in New Mexico, the United States, originally considered the epicenter of the first group of Native American hunters and gatherers in the New World. Moreover, Monte Verde yielded many interesting macrobotanical samples, including potato tuber skins (Dillehay 1989). The presence of "potato" in Monte Verde had important implications. First, it is the earliest archaeological record of "potato" in the Americas; second, the most widely cultivated potato in the world (the Chilotanum group of *S. tuberosum*) originated about 80–300 km southwest of Monte Verde (from Chiloe Island to the Archipelago of Chonos and Guaitecas); and, third, it rekindled peer discussions on the origin of the common potato cultivated in the temperate zones of the world, where only the long-day (or short-night) varieties of *S. tuberosum* became adapted, as in southern Chile.

The original taxonomic analysis of the potato remains found at Monte Verde indicated that they belonged to the wild species *Solanum maglia* (Ugent, Dillehay, and Ramirez 1987). This species is the only tuber-bearing wild potato known in the southern temperate zone of South America. However, further analyses of the starch grains of extant *S. maglia* samples (Spooner et al. 2012) showed various inconsistencies in the interpretation of the botanical results obtained at Monte Verde. Furthermore, *S. maglia* is found about 1,000 km north

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

© 2018 John Wiley & Sons, Inc. Published 2018 by John Wiley & Sons, Inc.

DOI: 10.1002/9781119188230.saseas0472

of this archaeological site. The archaeologists of Monte Verde also suggested that *S. maglia* was a staple food of the Paleo-Americans that occupied that southern region, but *S. maglia* is known to contain very high levels of toxic glycoalkaloids, which make its tubers not only very bitter but also poisonous, even after cooking. This confusion may have arisen from the general name “*malla*” given to “native potatoes” by the Mapuche people encountered by the first European chroniclers, later Latinized as *maglia*. However, the edible native potatoes grown by the Mapuche were probably introduced into southern Chile from Peru, Bolivia, or Argentina during the Late Archaic period, or possibly even later (ca. 2,500 BP) by migrant Mapuche groups from south-central Chile or southwestern Argentina.

The role of *S. maglia* as a possible progenitor of the Chilotanum group of *S. tuberosum* potatoes has been investigated with mixed results. Whereas potato taxonomists believe that *S. maglia* was not closely involved in the development of the long-day potato varieties of southern Chile (Chilotanum group), *S. maglia* was found to be phylogenetically related to this group of potatoes. Moreover, this molecular research definitely showed that the Chilotanum potatoes from southern Chile gave origin to the potato varieties grown in the temperate zones of the world. The Chilotanum potatoes were derived from the central Andean (Andigenum) *S. tuberosum* potatoes of southern Peru by further hybridization with a wild potato species (possibly *S. tarijense*), encountered as the Andigenum genotypes were disseminated into Chile through the Andean region of Bolivia and northwestern Argentina. These two groups, Andigenum and Chilotanum, constitute the *S. tuberosum* species of potato cultivated all over the world.

The paleoethnobotany of *S. tuberosum* in its center of origin (Peru) is rather limited (Ugent and Ochoa 2006) and debatable. The earliest potato remains were found at the site of “Tres Ventanas,” a group of three caves located at 3,925 m above sea level in the Chilca Canyon, 65 km southeast of the capital Lima. The caves were occupied from about 10,000 to 6,000 BP, during the Archaic period. Human, animal, and plant remains were found at different levels spanning over 9,000 years, with the potato samples dated to about 6,900 BP (initially dated to 10,000 BP).

Considering their age and the fact that the site is located in a very high and dry area, it is possible that these potato remains belonged to a wild potato species. The remaining archaeological sites where potato remains have been detected in Peru are dated to the Late Archaic period (4,000–3,200 BP), and are located on or close to the dry Pacific coast of Peru, where potatoes are not grown at the present time. This observation shows a tendency for the earliest macrobotanical remains of potato to be located predominantly in dry areas, where they were probably acquired and preserved, rather than cultivated. For instance, the coastal Casma Valley is formed by the basin of the Casma River, which flows across the coastal desert of the Ancash region of Peru. There, four archaeological sites—“Huaynuma,” “Pampa de las Llamas,” “Tortugas,” and “Las Haldas”—dated between 4,250 and 3,200 BP, yielded potato remains. The presence of potatoes and some cultivated plant species at these desert sites suggests that the potatoes found were already cultivated in more fertile regions of the nearby Andean mountain range. In the same Late Archaic period, the site of “El Paraíso,” located in the Chillón River Valley on the central coast of Peru, also contained potato remains dated to about 4,200 BP. In this case, the fertile Chillón valley could have supported potato production along its middle and high basin course, located 1,000–4,300 m above sea level. The remaining archaeological sites where potato remains or ceramics depicting potatoes have been found are also located along the arid Pacific coast of Peru, where cultivated potatoes (*S. tuberosum*) could have been imported from the bordering mid-altitude zones of the Andean mountains during the Current Era.

Modern cladistic analyses show that the Andean *S. tuberosum* landrace populations form a monophyletic clade, derived from the southern Peruvian members of the *S. brevicaulis* or *S. bukasovii* complex (Spooner et al. 2005), distributed mainly in the Pasco, Junín, Huancaavelica, Ayacucho, Cusco, and Apurímac regions of Andean Peru. The latest molecular taxonomy currently includes previously recognized species such as *S. chaucha*, *S. phureja*, and *S. stenotomum* in the *S. tuberosum* complex, which makes their identification in microbotanical studies more challenging. The new potato taxonomy proposal only recognizes three other cultivated

hybrid species of “bitter potato”: *S. ajanhuiri*, *S. juzepczukii*, and *S. curtilobum*. These species are usually cultivated at altitudes between 3,600 and 4,300 m above sea level in the Central Andes. The bitterness of these potato species is due to their high concentration of toxic glycoalkaloids, a defense mechanism against pests in general. Due to this trait and the fact that bitter potatoes possess a higher tolerance to frost damage than *S. tuberosum*, they cover about a third of the area planted to potatoes in the Peruvian and Bolivian altiplano. Bitter potatoes are transformed into edible products (“chuño” and “tunta”) by an ingenious natural process of freeze-drying practiced by early societies in the New World.

The bitter potato species *S. ajanhuiri* was formed by natural hybridization between *S. tuberosum* Andigenum and the wild potato species *S. megistacrolobum*. The latter species is distributed mainly in the Bolivian departments of La Paz, Cochabamba, Potosi, Chuquisaca, and Tarija at elevations between 3,700 and 4,100 m. *Solanum juzepczukii* was formed by hybridization of *S. tuberosum* Andigenum and the wild potato species *S. acaule*. This wild progenitor is distributed throughout the highlands of central Peru, but its populations are concentrated south of Lake Titicaca, in the Bolivian departments mentioned above. *Solanum curtilobum* was probably obtained from a cross between *S. tuberosum* Andigenum and *S. juzepczukii* (Spooner et al. 2007). Although the origin of these bitter potatoes indicates that these hybrid species were formed after the cultivated Andean potatoes of southern Peru, their center of origin seems to be located south and not north of Lake Titicaca, as *S. tuberosum* Andigenum.

The most important agricultural complex on the southern shores of Lake Titicaca was “Chiripa” (ca. 3,600 BP), considered the foundation of the first “Cultural Empire” in the Central Andes: “Tiwanaku.” This society expanded its dominion and influence north and south of the circum-Titicaca area, and contributed to the expansion of the Tiwanaku–Huari empire (1,500–1,000 BP) from northern Peru to northern Chile. The Huari tradition owes its development to the “Huarpa” culture (2,200–1,500 BP), one of the earliest agricultural complexes in southern Peru. The Huarpa integrated numerous farming settlements around

their capital “Nahuimpuquio,” and started the construction of agricultural terraces and hydraulic works in the highlands to incorporate the mountains of the steep Andean region into agriculture, over 1,500 years before the Inca emerged in Peru. The Andean potato may have been domesticated during the Archaic period of Peru (8,000–3,800 BP), but the existing archaeological evidence suggests that extensive potato cultivation in the Central Andes only took place in the Early Formative period (3,800–3,000 BP). Potatoes were widely cultivated in South America when the Spanish conquerors and chroniclers first arrived and saw potatoes in the central highlands of Colombia in 1537; in northern Ecuador in 1538; in Peru in 1539; in the circum-Titicaca area in 1552; and in the Guaitecas archipelago of southern Chile in 1557.

Rice

WEI-MING WANG

Nanjing Institute of Geology and Palaeontology,
Chinese Academy of Sciences, China

Rice refers to the cultivated grass species *Oryza sativa* (Asian rice) and *Oryza glaberrima* (African rice). As a staple food for over half the world's population, it is the predominant dietary energy source for 17 countries in Asia and the Pacific, nine countries in North and South America, and eight countries in Africa. Rice is the most important cereal grain with regard to human nutrition and caloric intake (Smith 1998). According to a report of the Food and Agricultural Organization of the United Nations in 2004, rice provides 20 percent of the world's dietary energy supply, while wheat supplies 19 percent and maize 5 percent.

Rice is normally an annual plant, but it can be grown as a perennial crop in tropical areas. Rice growth is relatively rapid. Rice can complete the process of germination, flowering, and fruiting within three to four months. A normal growth period lasts around 130–140 days, though a life cycle spanning a year is also possible. Therefore, it is possible to grow three crops of rice per year in some warm areas.

Rice cultivation is suited to countries and regions with high rainfall, as it requires ample water. However, rice can be grown practically anywhere, even on steep hills and in mountain areas by using water-controlling terrace systems, such as those in the Guangxi and Yunnan Provinces of South China. Although its parent species are native to Asia and certain parts of Africa, centuries of trade and exportation have made rice commonplace in many societies worldwide.

Traditionally, farmers plant young rice seedlings after controlled flooding of the fields. This method requires sound planning and the use of water dams and channels, but deters vermin and reduces the growth of less-robust weeds

which cannot grow underwater. Although flooding is not necessary for the cultivation of rice, all other means of irrigation require greater weed and pest control during the growing season and a different approach to fertilize the soil.

Rice plants can grow to 1–1.8 m tall, depending on the variety and soil fertility. They have long, slender leaves, which when young are very similar to some weeds. Farmers generally distinguish them based on the special auricle and ligule on the leaf. The small flowers are produced in a branched arching to pendulous inflorescence 30–50 cm in length. The panicle contains about 200–300 flowers, with each flower producing a single edible caryopsis. The grain is between 5 and 12 mm in length and 2 and 3 mm in breadth. Rice is wind pollinated or self-pollinating.

Early, mid-season, and late-season forms of rice have been developed which respond differently to day-length. The early, mid-season rice is insensitive to light, and will normally reach maturity regardless of when it is planted. Late-season rice is much more sensitive to day-length. It requires short day-length conditions to complete heading and grain filling. As such it is very similar to wild rice from which it is directly evolved.

Rice is generally cultivated in the paddy fields, but dry rice cultivation in upland areas is also practiced. The morphological difference between water- and land-grown rice is small, while the physiological difference is relatively large. Dry-grown rice produces lower yields but is adapted to grow with the minimum amount of water. Its stem and leaf are strongly heat resistant, and its developed root system is adapted to low water availability.

Paddy rice is usually harvested when the grains have a moisture content of around 25 percent. Harvesting can be carried out by the farmers themselves, but is also frequently done by seasonal labor groups. Harvesting is followed by threshing, either immediately or within a day or two. Subsequently, paddy rice needs to be dried to bring down the moisture content to no more than 20 percent to make it ready for milling.

Cooked indica rice is dry and loose, and suitable for making rice noodles, fried rice, and radish patties. The cooked japonica rice is sticky, and good for general use. However, both indica and japonica rice produce glutinous grains. The indica glutinous rice is slender in appearance, while the japonica glutinous rice is short and round. Both of them are white and opaque in color. The indica glutinous rice is usually used for making eight-treasure porridge and rice dumpling, and the japonica glutinous rice for wine and rice pudding.

Rice wine, also known as *mijiu* in Chinese, is an alcoholic drink made from rice, which is traditionally consumed at formal dinners and banquets, and used in cooking as well in Asia. It is also used within a religious and ceremonial context. Rice wine is made from the fermentation of rice starch that has been converted to sugar. Microbes are the source of the enzymes that convert the starches to sugars. Rice wine typically has an alcohol content of 18–25 percent alcohol by volume. Chinese alcohol predates recorded history. Dried residue (see ORGANIC RESIDUE ANALYSIS) extracted from a 9,000-year-old pottery at Jiahu site in east-central China implies that early alcoholic beverages made from rice, honey, grapes, and hawthorn were already being consumed by the Neolithic peoples.

Indica rice and japonica rice are the result of long-term adaptation to different ecological conditions, in particular temperature. Indica rice is mainly found in tropical and subtropical lowlands. It can tolerate both high temperatures and strong light levels. The grains are slender and nonsticky, and similar to wild rice. Therefore, it is considered to be the basic cultivated form, evolved directly from wild rice. Japonica rice has a wide distribution, typically in mountainous and temperate regions. It can tolerate cold and low light levels. The grains are short and round, as well as sticky. It is thought to have developed from indica rice.

There have been plenty of theories concerning the origins of domesticated rice in Asia. Some early suggestions considered that Asian rice was most probably first domesticated in an area between Assam in India to Yunnan Province in China, but evidence for this is still lacking. Genetic evidence shows that all forms of Asian rice, both indica and japonica, sprang from a

single domestication of the wild rice *Oryza rufipogon* that occurred 8,200–13,500 years ago in South China (Molina et al. 2011). Mapping rice genome variation suggests that this domestication occurred in the Pearl River valley region of China (Huang et al. 2012).

The increasing amount of data on early rice farming in the middle and lower reaches of the Yangtze River in China means that this region has become one of the most important places to trace the origin and development of rice agriculture (Normile 1997). Morphological studies of rice phytoliths (see PHYTOLITH ANALYSIS) from the Diaotonghuan archaeological site in the middle reaches of the Yangtze River show a possible transition from collecting wild rice to cultivating domesticated rice. A large number of wild rice phytoliths in a layer dating from 12,000–11,000 years ago indicates that wild rice collection was part of the local means of subsistence. Morphological changes of phytoliths recovered from layers dating from 10,000–8,000 years ago show that rice had by this time been domesticated (Zhao 1998).

The initiation of rice agriculture is believed to be linked to the establishment of more or less sedentary settlement patterns and the occurrence of pottery making. The warming climate after the last glaciation allowed the spread of wild rice northward, while a growing human population with increasing food requirements and the ability to store foodstuffs would have provided the right conditions to promote domestication (see DOMESTICATION). Evidence from the middle and lower Yangtze River area exhibits the transitional process from a hunting and gathering society to an agriculture-oriented society (Wang et al. 2010).

About 5,000–4,000 years ago, there was a rapid expansion of rice cultivation into mainland Southeast Asia, eastwards to the Korean Peninsula and the Japanese archipelago, and westwards across India and Nepal. Rice spread to the Middle East about 2,000 years ago. Rice was introduced to Europe through western Asia, and to the Americas through European colonization.

Oryza glaberrima, known as African rice, is native to West Africa. It is believed to have been domesticated from its wild ancestor *Oryza barthii* in the inland delta of the Upper Niger River some 2,000–3,000 years ago. The genome

of *O. glaberrima* has been sequenced (Wang et al. 2014). At present, African rice is being replaced by the introduced Asian rice. Some West African farmers, including the Jola of southern Senegal, still grow African rice for use in ritual contexts (Linares 2002).

African rice grows best on fertile alluvial soils, although it tolerates low soil fertility and can produce higher yields than Asian rice on alkaline and phosphorus-deficient soils. African rice is generally more tolerant to fluctuations in water levels, iron toxicity, infertile soils, severe climatic conditions, and human neglect, and exhibits better resistance to various pests and diseases than Asian rice. However, the grains are harder and shatter more easily than those of Asian rice. This means that African rice is less easily milled.

African rice was introduced to the New World during the days of the slave trade, and today is cultivated in parts of Brazil, Guyana, El Salvador, and Panama. African rice is still an important crop for small-scale farmers, who grow it for its nutty flavor and other culinary qualities. It is also used in rituals and in African traditional medicine.

By cross-breeding different kinds of rice, the earliest high-yield rice was cultivated by an American plant breeder, Henry M. Beachell, in 1966. But it was not until 1974 that the first hybrid rice varieties were released by a Chinese hybrid rice breeding expert Longping Yuan. As with other types of hybrids, hybrid rice typically displays heterosis or hybrid vigor so that it can produce up to 30 percent more rice when it grows under the same conditions as comparable high-yielding inbred rice varieties. Scientists from the Africa Rice Center managed to cross-breed African rice with Asian rice varieties to produce a group of interspecific cultivars called New Rice for Africa. Nowadays, high-yield crops, like hybrid rice, have become one of the most important tools for combating world food crises.

Genetically modified rice comprises rice strains that have been genetically modified. Rice plants have been modified to increase micronutrients such as vitamin A, accelerate photosynthesis, tolerate herbicides, resist pests, increase grain size, generate nutrients, improve flavors, or produce human proteins (Sharma and Sharma 2009). The natural movement of genes across species, often called horizontal gene transfer or lateral gene transfer, can also occur

with rice through gene transfer mediated by natural vectors. However, the cultivation and use of genetically modified varieties of rice remains controversial.

River Systems

ANDY J. HOWARD

Royal Holloway, University of London, UK

Rivers provide arteries of varying scale, allowing freshwater, sediments, and soluble elements to move from terrestrial uplands to the seas, thereby completing the hydrological cycle. Rivers are usually visible landforms on the earth's surface, but in soluble geologies such as limestone, or within glacial environments (see GLACIAL AND PERIGLACIAL ENVIRONMENTS), they can flow beneath it. On the surface, they may be constrained within narrow valleys where they inundate entire floodplains, or they may occupy wider valley floors, only part of which is subject to active river processes at any one time. The former courses of subterranean rivers can produce caves and fissures (see CAVES AND FISSURES) that provide important foci for subsequent occupation by both humans and animals and preserve sedimentary sequences (Woodward and Goldberg 2001), which allow paleoenvironmental reconstruction (see PALEOENVIRONMENTAL RECONSTRUCTION). In semi-arid and arid environments, ephemeral rivers occupy valleys known in the Middle East and North Africa as wadis, but they are only active after significant rainfall causes flooding (see FLOODING).

Water is essential for all life and rivers have provided resource-rich environments and corridors for animal and human migration since the earliest hominins emerged in East Africa around 4 million years ago. As modern humans moved from mobile, subsistence strategies to those focused around more sedentary agricultural lifestyles, the fertile plains of major systems, such as the Indus River, Yellow River, Nile, and Euphrates, became the birthplaces of ancient societies. Where water sources are scarce, humans have constructed irrigation systems linked to rivers to harvest floodwaters (Meister, Rettig, and Schütt 2016). As societies became ever more sophisticated, rivers and associated wetlands developed as

important foci for ritual and religious activity, including the votive deposition of objects (see BEHAVIORAL ARCHAEOLOGY). Since later prehistory, rivers have been a conduit for the trade and exchange of goods, which accelerated during the historic period. With economic growth came increasing river engineering, notably to harness water power and improve navigation and trade links.

Rivers are natural conveyors of, and sinks for, sediment and biological remains, and, as such, can form significant paleoenvironmental archives. Their energy levels and ability to transport sediment are governed by internal factors such as bed friction and channel gradients, as well as external factors such as climate and sediment supply. Historically, high water tables in valley floors globally have helped create anoxic environments where cultural and environmental remains can be well preserved within peat deposits (see PEAT DEPOSITS) or other fine-grained sediments, for example, causeways, platforms, trackways, and fishweirs. Such preservation provides opportunities for detailed paleoenvironmental reconstruction of climate, vegetation, and anthropogenic activity, using, for example, palynology (see PALYNOLOGY), chironomids, paleoethnobotany (see PALEOETHNOBOTANY), and archaeoentomology (see ARCHAEOENTOMOLOGY). However, intense pressure on contemporary groundwater resources via abstraction is resulting in the degradation of these fragile environmental resources, although hydrological modeling (see HYDROLOGICAL MODELING) can help to assess the potential for long-term preservation in situ.

Rivers also provide important records of pollution (see WATER POLLUTION) evidenced in the archaeological record through geochemical analysis of contaminated sediments associated with the mining of metalliferous ores. In northern Europe, the majority of historical contamination is associated with the industrial revolution (Audry et al. 2004), whereas elsewhere, for example the Levant, significant pollution records extend back into prehistory (Grattan, Gilbertson, and Hunt 2007).

DOI: 10.1002/9781119188230.saseas0509

The long-term evolution of river systems is underpinned by climatic cycles and geological uplift histories, the latter associated usually with tectonic or glacio-isostatic processes. During the Pleistocene epoch of the Quaternary timescale and the period associated with Paleolithic human activity, evidence of former river systems beyond the limits of icesheets is usually preserved as terrace sediments and associated surfaces, each representing a former floodplain subsequently isolated by fluvial incision. Each terrace provides a record of both erosion and sedimentation associated with discrete glacial–interglacial cycles, driven by astronomical changes in the earth’s orbit around the sun. These astronomical cycles and the aggraded river terraces can be correlated with oxygen isotope chronostratigraphy established within deep-sea sediments, thereby allowing global correlation of climatic periods and fluvial archives (Bridgland, Maddy, and Bates 2004).

Dating of Pleistocene terrace deposits is largely beyond the limits of radiocarbon techniques and usually relies on other methods. These comprise primarily: (1) the stratigraphic relationship, sedimentology, and altitudinal position of terrace deposits with respect to each other; (2) the identification of discrete faunal and floral assemblages within terrace sediments (see QUATERNARY LARGE-MAMMAL ZONES and QUATERNARY MICRO-MAMMAL ZONES); (3) the use of other absolute or relative dating techniques that estimate either the age of the sediments themselves or associated faunal remains, for example, optically stimulated luminescence (see OPTICALLY STIMULATED LUMINESCENCE), cosmogenics (see COSMOGENIC DATING), amino-acid racemization, and electron spin resonance (see DATING AND ELECTRON SPIN RESONANCE (ESR)). In tectonically active regions, the dating of lava flows interbedded within terrace sequences using isotopic techniques has also provided significant results. Until the 1970s, terrace chronologies were commonly dated by lithic artifact associations (see DATING (BURNT) LITHICS), though it is now recognized that such robust artifacts can be reworked through numerous terrace units, therefore requiring cautionary use (Bridgland and White 2015).

In northern and southern latitudes during glacial cycles, erosion and sedimentation within river valleys beyond extensive icesheets was

characterized by the deposition of sands and gravels within unstable, multichanneled braided systems. There was little in the way of organic sedimentation, reflecting the sparse vegetation cover, but aeolian activity often led to the reworking of sands and silts, which blanketed terrace surfaces with coversand and loess. Where permafrost was present, periglacial processes led to the development of ice wedges and cryoturbated horizons within the deposits. While organic sediments are sparsely preserved, they have the potential to provide insights into paleoecology and paleoenvironments.

During interglacial stages, sedimentation in northern and southern latitudes was characterized by deposition of silts, clays, and organic sediments (peat, gyttja) in single (meandering) or multichanneled (anastomosing) systems, reflecting stable, well-vegetated environments (see TEMPERATE ENVIRONMENTS). Such sediments can occur as discrete channel fills or as more widespread overbank deposits. The abundance of vegetation and generally low-energy conditions afford significant opportunities for environmental reconstruction.

Throughout the Paleolithic, hominins were hunter-gatherers, leaving little trace of their temporary encampments or evidence for their exploitation of environments. It is generally believed that hunter-gatherer groups spread more extensively into the northern and southern hemispheres during interglacials, often via river systems, whereas during glacials they retreated towards warmer refugia and favorable niche areas of southern Europe and the equator. During glacials, migration extended onto continental shelves that became dry-land as a consequence of icesheet expansion and globally lower sea levels; these now-submerged landscapes would have had their own network of rivers (Bicket and Tizzard 2015).

Buried within and upon river terrace deposits, the primary evidence of Paleolithic human activity usually comprises isolated finds or more abundant assemblages of stone tools, found by a variety of archaeological fieldwork, particularly where aggregate quarrying has been monitored for Paleolithic archaeology. Very rarely, terrace sediments have yielded extensive, well-preserved evidence for animal butchery on

former floodplains, as at Lynford in the United Kingdom (Boismier, Gamble, and Coward 2012).

For the last 10,000 years of geological time, an interglacial climate has prevailed, and for the first few thousand years the landscape developed naturally without significant anthropogenic interference. In northern and southern latitudes, temperate climates resulted in environments akin to those prevailing during earlier interglacials, providing rich resources for Mesolithic hunter-gatherers. The development of more sedentary lifestyles associated with farming in later prehistory led to deforestation of landscapes, resulting in soil erosion and colluviation; this, in turn, overloaded river systems with fine-grained sediment and resulted in alluviation (Brown 2009). Indeed, the thick alluvium of modern-day floodplains has no Pleistocene interglacial analog. Across Europe, statistical analyses of radiocarbon dates associated with Holocene river sediments have allowed episodes of erosion and alluviation to be correlated with climate change, with the greatest effects identified when humans have made landscapes susceptible to erosion through agricultural activity (Macklin, Jones, and Lewin 2010; see EROSION).

Elucidating the evolution of river systems and dovetailing knowledge of the associated archaeological record is best achieved using frameworks designed around geoarchaeology (see GEOARCHAEOLOGY) and geomorphological survey (see GEOMORPHOLOGICAL SURVEY). Geoprospection for Paleolithic remains requires a detailed understanding of Quaternary sedimentary records and formation processes (see FORMATION PROCESSES) due to the low population densities and hence limited impact of hominins on the landscape. In contrast, during the Holocene, human activity and population density increased exponentially, creating complex archaeological records that can only be unraveled using multiple approaches to archaeological fieldwork. During the early part of the twentieth century, geoprospection for postglacial archaeological sites in river valleys developed around the emerging discipline of aerial photography (see AERIAL PHOTOGRAPHY) and set-piece excavation. Now, increasingly sophisticated remote-sensing (see AIRBORNE REMOTE SENSING) techniques are available. These

include a range of multispectral and hyperspectral satellite imagery (see SATELLITE HYPERSPECTRAL AND MULTISPECTRAL IMAGING) and airborne light detection and ranging (LiDAR); terrestrial remote-sensing techniques include geophysical methods such as electrical resistivity (see ELECTRICAL RESISTIVITY) and ground-penetrating radar (see GROUND-PENETRATING RADAR). The sediments themselves also provide opportunities for dating control using a range of radiometric techniques (^{14}C , optically stimulated luminescence (OSL)), as well as opportunities for geochemical and mineralogical analyses to determine catchment erosion and sedimentation histories. Organic sediments preserved within abandoned river channels (paleochannels) and other floodplain wetlands provide further opportunities for environmental reconstruction through the analysis of proxy indicators of past climate, vegetation, and land-use such as pollen, insects, and macroscopic plant remains. However, river evolution has the potential to erode and/or further bury in-situ archaeological remains, affecting visibility and preservation potential (Howard and Macklin 1999).

Understanding the past evolution of river systems, their response to climate change, and how humans have interacted with them, both positively and negatively, is important since it can provide significant insights into how rivers and global societies will respond to future environmental change (Lewin 2012).

Sampling in Environmental Studies

JACQUI HUNTLEY

Historic England (retired), UK; University of Durham (honorary), UK

Environmental archaeology uses biological materials (pollen, fruits/seeds, wood, bird and mammal bones, invertebrates, etc.) as proxies for interpreting the landscape and economy of archaeological sites. These materials survive to a greater or lesser extent under suitable conditions but, with the exception of some bones and wood, are largely invisible at excavation. Therefore samples of sediment need to be taken and processed for the majority of these remains to be retrieved and studied.

The aim of sampling is to recover a reasonable representation of the remains present in that context. This entry outlines the thought processes involved in sampling, rather than delivering a prescriptive discourse.

The processes in determining a sampling strategy should be the same whether excavation is research-, teaching- or planning-led, although this can be difficult due to time and other resource limitations. It is essential that all project specialists help to develop initial aims and objectives. For example, excavation of an Iron Age farmstead in northern England is planned. The archaeologist is interested in its form and date compared with the large number of other known Iron Age farms in the region—whether it is enclosed, ditched or palisaded, and so on. Given all these other sites, the archaeobotanist knows that the charred plant remains will show use of spelt wheat and hulled barley, probably 6-row, but acknowledges that some samples will need to focus on confirming this (or not). They are interested in the fact that this site lies on a small promontory above an estuary, and would like to explore whether and how these coastal soils were used.

The size and nature of the sample will be determined by what is expected to survive (English

Heritage, 2011, Figure 2; see also FORMATION PROCESSES), as well as the research aims and objectives of the project.

What to sample seems an easy question at first. It could be every suitable context, followed by selecting those to take further once basic phasing (dating) is established, or it might target only those contexts with questions already defined. The first can be time-consuming and costly on a large excavation, although it offers the opportunity to answer new questions that arise as the excavation proceeds. The latter produces samples that should be valuable but is inflexible unless the excavators are aware of opportunities that turn up unexpectedly and act upon these. Other options include stratified systems of sampling every fifth or similar context or, indeed, using a randomized strategy for a mathematically rigorous scheme (see SAMPLING THEORY). Purely judgement samples taken ad hoc may be inappropriate unless a specialist is on-site as, for example, “interesting black material” could easily be coal or manganese on some sites, and of little value in addressing environmental questions. Most often a combination of stratified and judgement methods is used. It is important to sample the full range of context types, including those in areas apparently devoid of activity: those enigmatic “layers” with few or no finds. Evidence of absence can be valuable when investigating spatial patterns.

The next question is whether to process on-site or later in the laboratory. On-site processing with immediate assessment by an appropriately experienced specialist allows feedback and potential modification of the strategy. For example, a pit on an Iron Age site produces a few seeds whose types suggest it might be earlier Bronze Age, so more sediment would increase numbers recovered and reliability of results to test the initial interpretation. Processing later may give better quality control, but is inflexible.

The team will need to decide how much to process. For charred plant remains the aim is to recover at least 100–200 items from a context, although ideally nearer to 500 for statistical analysis. It is quite common to need 40–60 liters of

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

© 2018 John Wiley & Sons, Inc. Published 2018 by John Wiley & Sons, Inc.

DOI: 10.1002/9781119188230.saseas0512

sediment to achieve anything near this number for many sites in Britain. In northern England it has been calculated that 1–2 tonnes of sediment would often be needed; clearly this is rarely, if ever, possible or desirable. Thus many samples cannot offer a statistically valid interpretation. However, even small numbers of remains can be used to understand preservation or help to establish presence or absence at a site. These are samples processed by flotation to separate the light fraction of charred plant remains from the heavy mineral component, which itself can produce small bones from mammals, small mammal remains, bird and fish bones, and pot fragments, all of which can easily be missed during hand recovery.

In waterlogged and exceptionally arid deposits, concentrations of plant remains are often higher and 1–2 liters of sediment might well be sufficient to recover sufficient numbers. However, in such deposits the diversity (richness and evenness) of the target population needs to be considered. For example, contexts comprising dung from pastured animals can produce a low diversity of taxa which are undiagnostic or that cannot be identified beyond family level. These samples are processed by washing or dry-sieving them through a bank of sieves down to 250–350 microns in the laboratory.

Monoliths or Kubiena tins are used where intact stratigraphic sequences are needed to look at changes through time: pollen from naturally filled deposits, or from those where dumping may have occurred, like ditches (see PALYNOLOGY). Beetles and macroscopic plant remains are also examined in this way, although monoliths need to be large, with ca. 20 cm sections.

Once samples have been collected and processed, they need assessing as to their potential

to address the initial questions posed, but also to see whether new questions can be asked. It is therefore essential that this stage is undertaken by an experienced specialist who knows the sites and materials of that region for comparison. Full analysis, as then recommended, can be a better way to help train juniors where they can focus on specific samples and questions.

Overall, the three words that should always come to mind with sampling are: *why* sample, *what* to sample and *how* to sample. In this way the most appropriate samples should be taken for the materials expected, the site, and the questions being asked, thereby optimizing use of the available resources.

Sea-Level Change

INGRID A. K. WARD

University of Western Australia, Australia

Major dimensions of sea-level change

From an archaeological perspective, the main significance of past changes in global mean sea level (GMSL) is the influence on local and regional coastal geography. Consequently, the height of the ocean surface at any given location (relative sea level, RSL) is more relevant to coastal impacts of sea-level change than GMSL. The major causes of regional variability in sea level include climate-related factors (thermal expansion, salinity effects, internal ocean mass redistributions) and non-climatic geological processes (tectonic uplift or subsidence, glacio-isostatic adjustment, sediment compaction), particularly along soft-rock coastlines (Woodroffe and Murray-Wallace 2014). The resultant coastal configuration provides information to help understand changing resource availability over time, the potential for human migration, and coastal and aquatic adaptations, including the development of specialized technologies (Bailey and Parkington 1988).

The global rise and fall of sea level since the last interglacial (~125 ka BP), when sea level was several meters above present (Figure 1), has variously submerged and exposed bridging land masses between continents and islands. In many parts of the world, falls in RSL to 120 or 130 m below present during the last glacial period had a profound influence on the movement of modern humans, such as between Central Asia and North America across “Beringia,” between mainland Europe and the British Isles across “Doggerland,” and between South Asia and Australia, across Sundaland (Harff, Bailey, and Lüth 2016). As the glacial ice sheets began to melt around 20 ka BP, RSL rose rapidly in what is known as the post-glacial marine transgression. This transgression included the results of a series of rapid “meltwater pulses” at

approximately 14 ka BP (a rise of ~ 3.7 m/100 years), 11 ka BP (~2.5 m/100 years), 9 ka BP, and 8–7.6 ka BP (~1.2 m/100 years) (Figure 1), which affected the rate at which coastal areas were inundated and modified (Woodroffe and Murray-Wallace 2014). Such periods are of interest in terms of how past human occupants interacted with such rapid sea-level change and also how well the archaeological record has survived the changing interaction of the oceanic tide with the continental shelf and coastline.

By the end of the Pleistocene (11.7 ka BP), in most areas, sea level had risen approximately 60 m, and by 7,000 years ago was close to present levels (Figure 1). About 3 percent or 5 million km² of coastal land has been drowned since the Last Glacial Maximum (LGM) (22–20 ka BP). Across the globe, ancient flood stories may relate to post-glacial rising seas or to local sea-level fluctuations over the last thousand years (although many probably relate to more localized failure of ice and landslide dams). More tangible evidence of drowned villages and forests helps define local sea level over the last few millennia and indicates that catastrophic coastal change is an intrinsic part of the earth system. However, at the regional and global scale, the Mid- to Late Holocene experienced relatively little sea-level change compared to the last 150,000 years (Figure 1; see also Woodroffe and Murray-Wallace 2014). It is perhaps within this longer time context that the archaeological record of human migration and coastal and aquatic adaptation should be viewed.

Advancements in archaeological knowledge of sea-level change

Until the late twentieth century, archaeological links with sea level were mainly focused on the emergent records, particularly around the Middle East and Mediterranean. In the early to mid-twentieth century, evidence of lower sea levels and former landscapes was recorded from all sides of the North Sea in the form of submerged forests, Mesolithic-age barbed antlers and carved

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0526

Figure 1 Global (solid lines) and relative (dashed lines) sea-level curves for 160 ka to present, showing the Last Glacial Maximum (LGM) lowstand, major post-glacial meltwater pulses (MWP), and several important archaeological sites associated with lower sea levels (after Bailey 2010).

bones, and in 1957 with the discovery of the first Mesolithic-age submerged settlement, Tybrind Vig, off Denmark (Benjamin et al. 2011). In the Americas, mapping of potential submerged sites for cultural resource management within the Gulf of Mexico has led to a number of discoveries, including most recently an approximately 14,550-year-old megafaunal butchering site in the Aucilla River (Halligan et al. 2016). Along the south coasts of Africa, Spain, France, Italy, and Greece, submerged caves provide clues about early coastal occupation during times of lower sea level, including Blombos Cave, Vanguard Cave, and Cosquer Cave (Figure 1; see also Woodroffe and Murray-Wallace 2014). Ongoing studies in such areas are contributing to debates concerning the emergence of maritime societies, as well as the role of marine food resources in the evolution of the human brain (Bicho, Haws, and Davis 2011).

Until recently, it was thought that marine economies did not develop until the end of the Pleistocene, when the archaeological record begins to show evidence of dietary marine

fauna (see MARINE MOLLUSCS). This view is now challenged, supported by evidence for use of both dietary and utilitarian marine shellfish by early modern humans in Africa (PB13B, Klaises, Blombos Cave), Gibraltar (Gorham's Cave, Vanguard Cave), and the Mediterranean (Bajondillo Cave) from 130 ka BP or earlier, and by anatomically modern humans in South Asia by 42 ka BP (Niah Cave, Lena Hara) and Australia by about 45 ka BP or earlier (Bicho et al. 2011; Veth et al. 2017). Moreover, at several archaeological sites, changes in frequency of different shell species show good accordance with predicted coastal geomorphological and ecological changes, as a response to sea-level changes and an associated change in foraging strategy by humans. There is growing evidence that the intensified use of marine resources and development of associated technologies contributed to the demographic expansion of modern humans into parts of Southeast Asia, Australia, and the Western Pacific about 55–40 ka, the Americas around 13 ka ago,

and later the remote islands of Oceania about 4–1 ka ago (Bicho et al. 2011).

Early in the twentieth century, drowned terrestrial sites were prominent only in theory because the prospection techniques then available could not detect them (i.e., mainly SCUBA). The efficient mapping of such sites has become more important with increasing offshore development, and led to the Danish “fishing site location model” that acknowledged the importance of topography and bathymetry in predicting underwater coastal Mesolithic sites (Benjamin et al. 2011). Since the 1990s, the development and use of remote-sensing instruments, mainly for oil and gas exploration, offer possibilities for locating potential archaeological sites on continental shelves. In many parts of the world, the identification of a number of stillstands (i.e., periods of relatively static sea level) in the post-glacial sea-level curve helped explain the formation and evolution of estuaries, lagoons, barrier islands, coastal dunes, and other sedimentary coastal systems, allowing linkages between the terrestrial and marine record to be made (Woodroffe and Murray-Wallace 2014). These physical features, and any associated archaeological remains, mean that the depth contours obtained from (acoustic) bathymetric surveys can help predictive modeling of the locations of submerged archaeological sites, which is a major theme of current archaeological sea-level research (Harff et al. 2016).

Future directions in research, theory, and methodology

Sea-level research increasingly involves a cross-disciplinary approach involving archaeology, marine geology, marine ecology, molecular genetics, and human biology. Such research acknowledges that high-resolution spatial and temporal data are critical to understanding and preserving the human dimension of changes in sea level. At the same time, interdisciplinary studies of geologic and archaeological archives are providing a better understanding of the magnitudes, rates, and sources of GMSL and RSL rise, and in particular recent and future predicted accelerations of sea-level rise (currently estimated at 3 m/100 years) (Dutton et al. 2015). Estimates of GMSL

and RSL are derived from a range of proxy sources including oxygen-isotopic analyses of ice cores, corals, and coral reefs, mangroves and drowned forests, salt-marsh sediments and microfossils (e.g., foraminifera, testate amoebae, diatoms) (see DIATOMS), shoreline features (e.g., marine terraces, beach and chenier ridges, beachrock), tide-gauge records, and archaeological and historical sites (e.g., ancient ports, wells, ancient fish weirs) (Woodroffe and Murray-Wallace 2014). Of these, salt-marsh sediments, coral, and archaeological indicators provide the best means of correlating paleo-sea-level and historical data.

While records of local and relative sea-level change are obviously important to archaeology, sea-level data alone are often not sufficient for past and future archaeological reconstructions because it is not necessarily the magnitude of sea-level change that is critical but rather how it fluctuates. These fluctuations, and their precise nature—that is, whether linear or episodic—help determine the character of coastal and nearshore environments that people used, and potentially the timing of colonization (Bailey and Parkington 1988; Bicho et al. 2011). Such ideas contribute to changing perspectives on the habitats and resources used by hunter-gatherers during different phases of sea-level change, to the importance of changing marine ecosystems in human evolution, and, in turn, to the consequent impacts of humans on nearshore ecosystems (Harff et al. 2016). At the same time, a better understanding of human demographics and adaptation to past changes in sea level and coastal geographic change can inform our response to current and future sea-level change, including, for example, consideration of the vulnerability of coastal archaeological sites (Erlandson 2012). Hence, it remains important to continue to refine knowledge of patterns of past sea-level change.

Sheep and Goats

POLYDORA BAKER

Historic England, UK

Sheep and goats (ovicaprids) have been hunted or husbanded for food (e.g., meat, milk, and marrow), fibers, carcass by-products (e.g., fats, hides, horn, gut, and sinew), and dung. Sheep have been the subject of intense breeding for wool, while goats produce more milk and young and can fare well in poor environments. Both animals have been used as flock leaders, as pack animals, and for light traction. They also held and continue to hold important symbolic roles in many societies and religious faiths. The relative frequency of ovicaprids and the ratio of sheep to goats in archaeological sites can vary widely by area, period, and cultural and socioeconomic context.

Taxonomy and biology

Sheep and goats (Order Artiodactyla; family Bovidae; subfamily Caprinae) are similar in size and shape, but with key biological differences, including type and location of scent glands, coats, and horn shape. Wild sheep species include the mouflon, urial, argali, and snow sheep found in Asia and northeast Siberia, and the bighorn and Dalls sheep of North America. There are numerous wild goat species (tur, markhor, ibex, bezoar) found across Eurasia and in northeast Africa. Domestic sheep (*Ovis aries*) and goats (*Capra hircus*) are found worldwide, with genetics confirming that each descends from a single wild progenitor species, the Asiatic mouflon (*Ovis orientalis*) and bezoar (*Capra aegagrus*), respectively (e.g., Davis and Simões 2016).

Both genera are herbivores. Sheep are grazers, feeding on grassland vegetation, while goats browse on trees and shrubs, though both vary their diets depending on geographical location and season. Wild sheep are generally found in hilly regions and foothills, while goats prefer

steep, mountainous, and rocky terrain. They may move daily or seasonally to drink and feed. Marked seasonal weight loss may occur, including in domestic hill flocks (Worley et al. 2016).

Wild sheep and goats are gregarious, forming small cohorts of under 30 animals depending on sex, age, and breeding season, and occasionally congregating in larger herds. This characteristic would have assisted their domestication. In temperate zones, mating occurs mainly in the fall (when day-length decreases and the hormone melatonin increases), while in the tropics, where day-length varies little, reproduction occurs year-round. The gestation period in both species is about five months, though this, and fecundity, vary with breed and nutrition.

Methods of zooarchaeological study

Sheep and goats are mainly studied through osteology, with reliability in species identification depending on skeletal element, intraspecific variation, age at death, and geographical origin. Often bones can only be categorized as ovicaprid. Since the 1960s, many morphological and metric criteria have been developed to improve determination, with recent work focusing on examining reliability or expanding their application and interpretive potential (e.g., Davis and Simões 2016).

Population reconstruction based on age at death (from bone fusion, and tooth eruption and wear) may suggest a focus on particular products and forms of management, though mixed-husbandry systems are often the norm (Vigne and Helmer 2007). Bone fusion occurs in a consistent sequence, but happens earlier in females and is delayed in castrates (Popkin et al. 2012). Timing of dental eruption shows much less variation between sexes and this offset holds potential for characterizing management. Tooth wear can be particularly variable in older animals, influencing the reliability of derived mandible stages (Worley et al. 2016). Species and sex distinction greatly enhance interpretation of age profiles (Mainland 2006; Vigne and Helmer 2007).

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

© 2018 John Wiley & Sons, Inc. Published 2018 by John Wiley & Sons, Inc.

DOI: 10.1002/9781119188230.saseas0532

In wild animals, the bones of males are considerably larger than those of females, but in domesticates this differential is reduced and sex distinction is complicated by castration, which leads to longer and more slender limb bones. Sex distinction can also be obscured by metric variation between populations (e.g., breeds), so population “uniformity” needs to be assessed to make valid interpretations (Popkin et al. 2012). Where sufficiently intact, horncore or pelvis shape may be diagnostic of sex.

Bone size and shape can inform on domestication and husbandry, breed development, health, and physiological demands (pregnancy, lactation). The log-ratio method—comparison with measurements of a “standard” individual or population average—is a common analytical approach. Multivariate statistics have been used to confirm metric criteria (e.g., Popkin et al. 2012).

Domestication and diversification

Domestication (see DOMESTICATION) of sheep and goats probably occurred on many independent occasions in the Northern Fertile Crescent, in the mid-ninth millennium BCE (Davis and Simões 2016). Diversification would have followed rapidly as animals were moved, adapted to new environments, and were selected for specific traits. Numerous, probably regional varieties of sheep are described by classical authors, and zooarchaeological data have contributed to debates regarding timing of these and later livestock “improvements” (Davis 2008).

Early domesticates were similar in size and shape to their wild counterparts. Horns were among the first traits to change, for example from the long and scimitar form in wild male goats to a twisted, helical shape in domesticated animals. Hornless individuals are rare in mouflon and all goats, but evident in Chalcolithic images of domestic ewes. Some breeds have multiple horns. Other skeletal changes include reduction in limb bone length and lengthening of the tail. Analysis of astragalus measurements indicates greater bone robustness and shape variation in sheep, which may reflect more intensive selective breeding for wool and meat, compared to goats (Davis and Simões 2016).

Wild goats and sheep both have coarse hairy outer coats (kemps) and softer insulating undercoats. In sheep, the naturally molting short fibers of the undercoat have been developed through selective breeding into fleeces of varying length and quality; in primitive breeds, wool may be hairy and is plucked rather than shorn. Domestic goats have remained primarily hairy, but a few breeds produce substantial fine-quality fleeces, for example Angora and Cashmere. Early domesticates were probably dark/tan colored, as are wild animals and primitive breeds such as the Soay. Wool colors, from pale tan through to gray and black, have been identified in Bronze Age textiles, with a “new” nearly white type evident at Middle Bronze Hallstatt (Rast-Eicher 2014, 194).

Use

Sheep and goats may be raised for consumption at a young or “prime meat” age, or consumed following use for breeding, dairying, or wool production. In some societies, ovicaprid meat was preferred over that of other species. For example, the size of sheep increased during Islamic rule in Portugal, which along with younger slaughter (compared to earlier or later periods) suggests that sheep were bred to provide a greater amount of mutton and lamb, much appreciated in Arab cuisine (Davis 2008).

Ovicaprid milk can be used to produce cheese, yoghurt, and butter, with productivity varying between species, breeds, and environments. Dairy production (see DAIRYING) may be indicated by high representation of adult females, and surplus young killed to free-up milk supply, and through residue analysis (see ORGANIC RESIDUE ANALYSIS). In early Neolithic sites in France, goats may have been kept for milk, while sheep show a more mixed use (Vigne and Helmer 2007).

Goat hair and sheep’s wool are used for clothing, containers, and textiles (see TEXTILES). The wool industry was a key driver of the European medieval economy, evident in the high ratios of sheep (and ovicaprids) in bone assemblages. Historic records indicate that large numbers of males were castrated in order to improve the quality (finer, less greasy) and volume of fleeces, but their identification remains a key challenge

in zooarchaeology (Davis 2008; Popkin et al. 2012).

Bones in cremations and temples or shrines may show a concentration on a single species, restricted age groups, and body parts. Deposits of sheep and goat astragali can include hundreds of bones, their abundance and frequent modification suggesting ritual and secular (e.g., gaming) uses.

Management

Ovicaprids are managed in a variety of ways including nomadic, semi-nomadic, and transhumance pastoral systems, and in some cases supplementary foddering. Pasturing of sheep and goats on crop stubble and fallow land to improve soil fertility has long been an important seasonal activity for transhumant herders and agropastoralists.

Tooth microwear and biomolecular methods (see ZOOARCHAEOLOGY AND ANCIENT DNA and ZOOARCHAEOLOGY AND STABLE ISOTOPES) can inform on livestock management. Microwear analysis shows that grazing, browsing, and foddering of sheep and goats leave characteristic traces on tooth enamel, reflecting abrasion by food and soil ingested prior to death (Mainland 2006). At Neolithic Catal Hoyuk (Turkey), microwear and oxygen isotope analysis suggest that herds were pastured year-round near the settlement, using an outfield system including river valleys, and births were scheduled to coincide with optimal food availability in late spring. Farmers attempted unsuccessfully to vary birth season to early spring, while herd diet gradually shifted to clean, drier, grassy food, possibly through the use of more distant pastures or changes in foddering (Henton 2012).

Various pathologies may be linked to animal management. Horncore depressions and thinning of bone in ewes may reflect physiological stress during pregnancy and lactation. Osteophytes on the elbow joint and metapodials have been linked to penning, crowding, use of crooks, and uneven terrain. Overgrazing and ingestion of soil and harmful weeds may result in oral injury, such as alveolar recession, infection, and tooth loss.

New and future directions

Genetic analysis can allow secure distinction between species and continues to be instrumental in exploring domestication. Zooarchaeology by mass spectrometry (ZooMS) is based on a method of collagen peptide sequencing. It can also distinguish between wild and domestic sheep and goat species using very small samples and has been highly successful in the study of ancient parchments (Fiddymment et al. 2015). Baseline research in biochemical markers, including isotopes, is a priority for reliable interpretation of diet, mobility, and trade. Computer modeling has recently been used to investigate the role of domestication in disease transmission among humans and goats.

Sorghum and Pearl Millet

CHRIS J. STEVENS and DORIAN Q FULLER
UCL Institute of Archaeology, UK

Sorghum and pearl millet are widespread and important cereals in indigenous African agriculture (Harlan 1992), and they are also widely cultivated in India, mostly in the hot dry plains of southern and western India (Figure 1). Both are tall, thick-stalked cereals, often growing to 2 m or more in height. Both also are grasses with the C_4 photosynthesis, and as such are drought tolerant and well adapted to semi-arid savannah environments.

Pearl millet is arguably the most arid-adapted crop in the world, being grown along the southern margins of the Sahara, and reaching maturity sometimes on just 250 mm of rainfall, producing a crop within as little as three months (Brunken, de Wet, and Harlan 1977; Neumann et al. 2012). Various varieties or races of pearl millet are distinguished by how quickly they mature, the amount of tillering and branching, the size, shape, and compactness of the inflorescence, as well as the grain size, color, and shape.

Sorghum can be grown with as little as 300 mm of rainfall, but is considered most productive in areas with 500–800 mm of annual precipitation. As with pearl millet, many distinct varieties exist, differentiated particularly by their panicle shape and density, along with the size and shape of the grain, and the length and character of the glumes surrounding them. For sorghum these races often relate to the ecological zones in which they are found, with races such as *guinea* with large open loose panicles being associated with the rainforest zone, while is more commonly cultivated within drier habitats. Differentiation and dispersal in Asia has also included the evolution of Chinese Kaoliang sorghums, with tight-fitting hulls but having genetic similarities to free-threshing forms recorded in India. Kaoliang sorghum extends to temperate conditions in northeast China, Korea, and Japan to nearly 40 degrees latitude.

Regarding the wild ancestors of pearl millet and sorghum, the situation has been greatly complicated by the complex history of taxonomy that has existed for both species. In particular, the likelihood of a great many introgressions having occurred between wild and domesticated populations as both crops spread throughout the African and later Asian continent over the past 5,000 years has further added to this problem. The wild ancestor of sorghum using the binomial system is *Sorghum verticilliflorum* (Steud.) Stapf. or *Sorghum arundinaceum* (Desv.) Stapf (and using the binomial system syn. *Sorghum bicolor* subsp. *verticilliflorum* (Steud.) de Wet ex Wiersema & J. Dahlb.). Genetic work strongly suggests that modern cultivars are most strongly aligned with wild sorghum populations within central and northeast Africa (Fuller and Stevens 2018). The wild ancestor of pearl millet is attributed to *Pennisetum violaceum* (Lam.) Rich, although many papers refer to *Pennisetum glaucum* ssp. *monodil* (following syn. *Pennisetum americanum* subsp. *monodii* (Maire) Brunken). The likely origin of the wild progenitor lies within the Sahelian regions of West Africa.

Archaeological evidence indicates that sorghum was widely gathered as a wild food resource during the Early and Middle Holocene in the central and eastern Sahara under wetter conditions associated with the African Humid Period (ca. 14,800–5,500 years ago). These earliest finds of gathered wild sorghum include specimens from Egypt, Sudan, and Libya (Fuller and Stevens 2018). In terms of evidence for domestication (see DOMESTICATION), the earliest evidence for morphological change brought about by human cultivation is from chaff remains in ceramics from the eastern Sudan (near the Atbara River) between 3500 and 3000 BCE, associated with predominately forager-pastoralists who still had a strong reliance on hunting. After this, the archaeobotanical record (see PALEOETHNOBOTANY) in Africa is sparse, but sorghum had reached the Niger River basin by the mid- to first millennium BCE (Fuller and Stevens 2018). Sorghum was presumably an important crop

DOI: 10.1002/9781119188230.saseas0542

Figure 1 Distribution of traditional/pre-colonial areas of cultivation (hatched) for sorghum (*Sorghum bicolor* (L.) Moench.) (above) and pearl millet (*Pennisetum glaucum* (L.) R. Br.) (below). Sites with the earliest finds of domesticated types are denoted by asterisk.

prior to this in the savannas, and had become established as a major cereal in the Nubian Nile valley within the final centuries of the first millennium BCE, during the Meroitic Kingdom, where it is associated with irrigated summer cultivation that alternated with winter cultivation of cereals like wheat or barley (Fuller 2014).

Pearl millet (bulrush millet) has been found occasionally as a wild food among central Saharan foragers of the Early Holocene, but emerged as a crop along the southern Saharan fringes of western Africa. The earliest evidence for domesticated types comes from northeastern Mali dating to around ca. 2500 BCE. Finds to the west from Mauritania dating from the early second millennium BCE may represent a separate domestication process, while finds between 2000 and 1500 BCE

in central Mali, Ghana, and Cameroon attest to the spread of pearl millets throughout the western Savannas (Zach and Klee 2003; Manning and Fuller 2014). Around 400 BCE, pearl millet has been found on sites located today within the damp tropical rainforest areas of southern Cameroon, in wet environments where the crop cannot be grown today. This was made possible by a climatic shift dating to around 2,500 years ago, in which winter dry seasons became more pronounced in central Africa, leading to the establishment of more savannah elements in the rainforest zone (Neumann et al. 2012).

In eastern Africa, the spread of pearl millet is strongly tied to the spread of sorghum, and both have been linked to groups speaking Eastern Bantu and Nilo-Saharan (Central Sudanic and

Nilotic) languages. These are the earliest cereals of crop cultivation known in eastern Africa, although pastoralism without crop cultivation may be as much as 3,000 years earlier. Early finds near the African Great Lakes are from the first centuries CE, while on the east African coast (coastal Kenyan) and nearby Tanzanian islands these cereals were cultivated by 600 CE (Crowther et al. 2016). Shortly thereafter, both of these cereals reached southern Africa associated with the spread of Iron Age agropastoralism.

Despite the apparently late spread of sorghum and millet agriculture throughout much of sub-Saharan Africa, both these crops have been shown to have reached tropical Asia shortly after domestication. Pearl millet and sorghum, as well as some evidence of Africa beans, are present on archaeological sites in Gujarat, India by ca. 1700 BCE, and they are found in the Ganges plains and in southern India by around 1500–1000 BCE (Fuller 2003). Such evidence indicates an early translocation of African crops to tropical savannah environments of India via maritime contacts, most likely around the Arabian Peninsula, at a very early date, the process for which was been a recurrent issue of discussion and debate among archaeologists.

The evolution of varietal differentiation, which taxonomists identify as races, is of some interest in tracing the movement of both these crops. These races are partly geographical, but also reflect both conscious and unconscious selection for different physiological characteristics, particularly with regard to the nature of the inflorescence and grain. In the wild form and among the more primitive cultivars, grains are tightly clasped in husks, and hence require dehusking after the spikelets have been threshed to release the grain. But in both species, free-threshing varieties have evolved in which the grains are no longer fully enclosed within the husk and protrude from the spikelet, hence no longer requiring dehusking. In sorghum, free-threshing varieties evolved at least three times in different geographical races, referred to as *durra*, *guinea*, and *caudatum* (Harlan 1992; Fuller and Stevens 2018). In pearl millet, hulled forms are grouped within the widespread primitive race *typhoideum*, whereas other forms are all free-threshing (Brunken et al. 1977). While all pearl millet inflorescences are dense and compact, facilitating harvest, sorghum races have

evolved after domestication from loose panicles to much denser, compact inflorescences. Among the densest, tightest panicles, with free-threshing grains, is the sorghum race *durra*, thought to have evolved early in India and then dispersed back to Yemen and northeast Africa (Sudan) around 2,000 years ago.

Today, sorghum is consumed in a great many ways, including as gruel, beer, stiff porridge, and flat breads, while certain varieties can be toasted in a similar fashion to popcorn. In China, following traditions of sticky rice and millets, sticky forms of sorghum have been bred and used in a similar manner within local cuisines. While sweet-stemmed varieties of sorghum, *Sorgos*, have a long ancestry in Africa and India where they are used for fodder, they have been bred during the nineteenth century within the United States for production as a sweet sorghum syrup.

Pearl millet has similar uses to sorghum, being prepared as gruels, porridges, flat breads, and beer. However, it is worth noting that the germ or embryo ratio to grain in pearl millet is much higher than within many other cereals, and as such it yields relatively less flour with grinding. However, the heads of pearl millet can also be steamed and/or roasted and consumed in a similar manner to corn-on-the-cob or sweet-corn.

Spices

SABINE KARG

Free University of Berlin, Germany

Spices improve the taste of our dishes but also have properties that promote human health. As will be shown in this entry, the use of spices in human nutrition has a long tradition stretching over many thousands of years. Although spices were not used extensively during the last hundred years, at least in the western world, thanks to the modern globally inspired kitchen they have experienced a comeback. While salt (sodium chloride) might be considered a spice by some, it is an inorganic substance rather than of plant origin and therefore outside the scope of this entry. When thinking of spices, many of us think of pepper (*Piper nigrum*), chili (*Capiscum annum*), cinnamon (*Cinnamomum verum*), and cloves (*Syzygium aromaticum*): in other words, with something having an exotic taste! Not many of us consider that herbs like marjoram (*Origanum majorana*), thyme (*Thymus vulgaris*), and dill (*Anethum graveolens*) also fall under this category. Seeds such as those of pepper, whole fruits such as chili pods, tree bark such as cinnamon, and leaves such as bay (*Lauris nobilis*) are used to flavor our daily meals. It is not only the taste but also the effect on our digestion system, our blood pressure, and our heart activity that make the spices worth a closer look. Spices can be used as aphrodisiacs and as preservatives to help keep food free of bacteria and mold, and, last but not least, many spices are used for their particular type of fragrance, processed into perfumes or burnt to produce aromatic smoke.

Applying archaeobotanical methods, it is possible to obtain evidence for the long-term use of spices. The most common procedure is to take soil samples during the excavation and analyze them in the laboratory by washing the sample with water using sieves with mesh sizes down to 0.2 mm. The residues in the sieves are then screened under a binocular microscope, and the selected

plant macroremains such as seeds, fruits, leaves, and threshing remains are then determined by comparison with modern botanical reference collections (see PALEOETHNOBOTANY). Food residues in ceramics and equivalent containers are studied by applying microscopic methods in order to detect visible plant microremains, such as starch grains (see STARCH GRANULE ANALYSIS) and phytoliths (see PHYTOLITH ANALYSIS). By applying chemical methods, as, for example, mass spectroscopy or newly developed analytics in biomolecular science, the main components of food and drink such as lipids or fatty acids can be traced (see ORGANIC RESIDUE ANALYSIS).

Recent archaeobotanical finds of chili pepper in the New World indicate that this is one of the oldest spices, with evidence of cultivation 6,000 years ago. This is based on phytolith records of chili from seven excavated sites, both in the Amazon basin and on the coast of Ecuador (Perry 2015). Since Columbus discovered America, chili has spread around the whole globe and plays an important role in both the Asiatic and eastern European kitchen.

Exotic spices such as pepper, cardamom (*Elettaria cardamomum*), cinnamon, and nutmeg (*Myristica fragrans*) have their origins in the subtropical and tropical regions of Southeast Asia. The beginnings of their cultivation are still not properly explored, although it has been established that spices were traded from these regions to Egypt from at least the second millennium BCE (Cappers 2006; Van der Veen 2011). Even the transport of living spice plants is shown on the reliefs that are depicted at the walls of the temple of Deir al-Bahri which is situated close to Egypt's Valley of the Kings. This is the grave monument of the female pharaoh Hatshepsut who ordered the transport of living myrrh trees from Punt to Upper Egypt around 1495 BCE. Punt was most probably located in northern Somalia. Written sources also exist from this time period describing the medical properties of spices. The most famous is the transcribed Papyrus Ebers. These sources prove that people knew about the antibiotic properties of garlic, for example, even by this early date.

Direct evidence for the consumption of wild collected garlic (*Allium* spp.) is available in the form of pollen (see PALYNOLOGY) recovered from 6,000-year-old human feces (see COPROLITES) that were found in several of the UNESCO lake dwelling sites in the circum-alpine region of central Europe. Wild garlic was clearly collected and frequently consumed by these early farming communities. A belief in the potency of wild garlic is suggested by the numerous finds of cloves, especially in women's graves dated to the first millennium CE that have been excavated in northern Europe (Karg et al. 2014).

During the first millennium BCE, herbal medicine flourished in Greece. The most famous book from this time is the *Corpus Hippocraticum* written by Hippocrates who lived between 460 and 370 BCE. He describes 230 different medicinal plants. Some years later, the father of botany, Theophrastus (ca. 371–287 BCE), wrote ten books concerning the *Enquiry into Plants*, of which nine have survived. Spices from Asia such as cinnamon and cardamom are described in these books (<https://en.wikipedia.org/wiki/Theophrastus>). Spices and herbs were also so much appreciated in ancient Rome that they were used as valuables and a means of payment: for example, pepper. The Roman legions introduced some of the spices to central and western Europe (Orengo and Livarda 2016), while along the Silk Road, which was the trading route from China to Europe for many centuries, spices were exchanged with other goods such as silk, silver, and fur. Via this route many spices were transported to Europe during the first millennium CE.

Archaeological spices can best be recovered from storage facilities or latrines in which human excrements are often mixed with kitchen refuse. Latrines were normally dug deep into the ground and the archaeological layers that built up in them are therefore preserved under anaerobic conditions that exist below the permanent modern water level, meaning that organic material is perfectly preserved for thousands of years. Depending on the local climatic circumstances, plant remains can also be preserved through desiccation, for example in desert regions. In wetter climates, the chances of finding plant remains preserved through desiccation is much reduced and only occurs in special circumstances, such as within coffins or closed metal

containers (Karg et al. 2014). Charred records of spices are generally few and far between, except for excavations of kitchens or storage areas.

Besides archaeobotanical finds dated to the first millennium CE, written documents describe the cultivation of useful plants. The best-known sources for central Europe are:

- the *Capitulare de Villis* (ca. 800 CE);
- the monastery plan of St. Gallen (ca. 820 CE);
- the *Hortulus Walahfried Strabo* (ca. 830 CE).

In the *Capitulare de Villis*, 89 vegetables, fruit trees, and spices that should be planted in enclosed gardens are listed (Strank and Meurers-Balke 2008). Spices that are both recorded in the form of archaeobotanical finds in northern Europe and named in the *Capitulare de Villis* are published in Karg (2014) (Table 1). Precise information about the use of herbs for medicinal purposes is described in the writings of Hildegard from Bingen who lived during the twelfth century in central Europe. Throughout the Crusades during the thirteenth century, knowledge about spices was spread widely. The ancient trading centers in northern Egypt (Cairo and Alexandria) were superseded by Venice, Genoa, and Pisa. These towns became very prosperous during the medieval period due to the cleverness of the spice traders. It is said that one pound of saffron (*Crocus sativus*) had the same value as one horse, one pound of ginger (*Zingiber officinale*) was equal to one sheep, and pepper was compensated with gold.

The riches that could be gained by trading with spices triggered the voyages of discovery. When Vasco da Gama returned from India in 1499 with ships loaded full of spices, the Italian dominance was set to end. Now, it was Portugal that declared the prices for spices. A cinnamon monopoly guaranteed high profits which were used for financing more voyages. It was with the discovery of the New World that new spices such as allspice (*Pimenta dioica*), vanilla (*Vanilla planifolia*), and paprika and chili (different forms of *Capsicum annuum*) were introduced to Europe. In Spain, the cultivation of paprika occurred rapidly following its introduction and spread from there.

The spice trade was also a highly political affair. This is seen by the fact that in 1602 the Dutch founded the first public limited company of the world, the Dutch East Indian Company, which held the monopoly in the trade of nutmeg and cloves.

The global spice market, which started with the discovery of the Americas some 550 years ago, can be seen as one of the triggers for European expansion. Shipbuilding yards and warehouses boomed, exotic dishes were promoted in new cookery books, and new food traditions developed. Set against the profit of the western world, it is a tragic history of the numerous colonies, battles and wars, exploitation of local people, and destruction of natural environments. The end of World War II meant the end of the spice monopolies. However, today many spices still play an important socioeconomic role in their countries of origin. The story of how, where, and why the know-how of intensive spice production began and developed should receive much more attention in the future before it falls into oblivion.

Starch Granule Analysis

ALISON CROWTHER

University of Queensland, Australia

Starch granule analysis is a microbotanical technique used by archaeologists to document past uses of plants by humans. Starch granules are composed of carbohydrates and are produced by plants as an energy reserve. They are found in large quantities in many of the plants consumed by humans as food, including underground storage organs (roots and tubers) such as potato, yam, and cassava; grains such as wheat, rice, and maize; fruits such as banana and breadfruit; and various nuts (Figure 1). Variations in the size and shape of starch granules between plants can enable the identification of specific botanical taxa. In some cases, plants, where other remains, such as seeds, phytoliths (see PHYTOLITH ANALYSIS), or pollen, are undiagnostic or do not preserve well, produce starch, making this technique an important addition to the paleoethnobotanical toolkit (see PALEOETHNOBOTANY), particularly in tropical regions where subsistence typically relies on vegetative rather than grain crops. Starch granules can be found archaeologically as residues on the surfaces of stone tools, pots, and other food-processing implements, in sediments from agricultural features or activity areas, or trapped in dental calculus, coprolites (see COPROLITES), stomach contents, and charred or desiccated food remains. As such, starch granule analysis can provide complementary and unique paleoethnobotanical insights into many aspects of past human behavior, including diet, plant-processing activities and their on-site spatial arrangements, artifact function, early agriculture, and crop dispersal histories. The study of ancient starch granules generally requires chemical extraction from the source material and the use of a light microscope for identification (see OPTICAL MICROSCOPY) (Torrence and Barton 2006).

Starch granules are mainly composed of two polysaccharides, amylose and amylopectin, as

well as minor quantities of lipids and proteins. Amylose (which has a linear structure) and amylopectin (which is highly branched) are arranged within the granule in regular, alternating amorphous and crystalline layers, which accumulate concentrically around a growth initiation point known as the hilum. The high degree of molecular and crystalline order within the granule gives starch granules semicrystalline properties. As such, granules display birefringence and form a Maltese-shaped extinction cross through the hilum when viewed with a cross-polarized light microscope (Figure 1b, d, and f). These features provide the main optical properties used to recognize starch granules. Storage starch granules form in specialized plastids called amyloplasts, where they can occur either as single “simple” granules up to 200 μm in size when mature, or as compound aggregates. Starch is also produced in chloroplasts within stems, leaves, and other photosynthetic tissues; unlike storage starch, such starch is synthesized on a daily basis and usually small ($<5 \mu\text{m}$) and morphologically nondiagnostic (Haslam 2004).

The attributes recorded to differentiate and identify starch granules include size, overall shape in both two- and three-dimensions (e.g., round/spherical, ovoid/ovate, polygonal/polyhedral), and variations in the granule outline, position of the hilum, distortions of the cross, the presence or absence of surface facets, internal fissures, and growth rings, and whether or not compound granules are present (Torrence and Barton 2006; see the International Code for Starch Nomenclature (ICSN 2011) for standardized morphological descriptors). Starch granule identification usually relies on direct comparisons between these features in archaeological and reference assemblages constructed from local plant flora in the study region. Multivariate methods have been explored as a more objective means of starch identification (e.g., Coster and Field 2015).

One of the more contentious aspects of ancient starch concerns preservation, with mechanisms contributing to long-term survival and diagenesis (see DIAGENESIS OF BONE and TAPHONOMY) still

Figure 1 Images of starch granules from common food crops. (a, b) Potato (*Solanum tuberosum*, tuber). (c, d) Bread wheat (*Triticum aestivum*, seed). (e, f) Lentil (*Lens culinaris*, seed). (Scale bars are 20 μm; b, d, and f are in cross-polarized light).

not fully understood. Archaeological studies demonstrate that granules can survive long periods (at least 200,000 years in mineralized calculus deposits) (Henry, Brooks, and Piperno 2011) in a range of depositional settings, despite their susceptibility to degradation by various physical, biological, chemical, and thermal processes. These processes include enzymatic hydrolysis by soil-borne microorganisms, mechanical attrition

by movement or compaction of the depositional sediment, stress fracturing from freezing or repeated cycles of wetting and drying, chemical dissolution caused by very acidic or alkaline conditions, and thermal decomposition caused by exposure to extremely high dry heat (>180 °C), or moderate heat (>40–50 °C) in the presence of moisture (Haslam 2004). These processes can affect starch survival prior to deposition

in the archaeological record such as during plant processing, as well as after deposition. The susceptibility of starch to degradation varies within and between plants depending on the granule's intrinsic species-specific properties (e.g., shape, size, composition), which creates many challenges for archaeologists attempting to reconstruct past assemblages from surviving altered compositions.

The main survival mechanism cited by archaeologists draws on the observation that starch granules appear to preserve best in protected microenvironments, such as embedded in pits and cracks on artifact surfaces, or encapsulated in mineralized dental calculus, charred residues on pottery, or soil aggregates. Desiccating or anaerobic environments and the presence of certain microbe-inhibiting compounds such as metals (e.g., copper, manganese) and tannic acids in the depositional environment may promote starch survival (Haslam 2004). Starch burial experiments have generally supported these observations, but have highlighted the highly variable nature of decay depending on local depositional conditions. Decay rates have been shown to slow down over long depositional periods, particularly in stable burial environments in which starch granules and their degrading mechanisms are more likely to reach equilibrium.

Food processing can modify, and in some cases completely destroy, starch, affecting its deposition and survival in the archaeological record. Activities such as cooking, grinding, and fermenting, which are often essential for transforming starch-rich plants into an edible form or for preparing particular ingredients such as flours, can impart characteristic alterations to the morphology of starch granules (Babot 2003). Importantly, however, these degradation patterns can help archaeologists identify such culinary behaviors in the past. For example, starches recovered from grindstones or pounding tools often display modifications such as cracking, tearing, and breakage, as well as roughened surface textures caused by mechanical processing. During fermentation, starch-specific enzymes called amylases break down the granule's concentric growth layers, sometimes leaving characteristic corrosion channels, as observed on starches in ancient beer-brewing residues. The most extreme

alterations to starch granules occur during cooking, which can cause granules to swell, lose their structure and birefringence, and eventually disintegrate. Intact cooked starch granules can nonetheless still be recovered from food residues on pottery and dental calculus, though their taxonomic identification is usually restricted owing to the loss of gross morphology.

Analyses of starch residues preserved on the used surfaces of archaeological stone tools and ceramics have drawn on these characteristic alteration patterns to provide complementary information about the functions of food-processing technologies. In some cases, these studies have demonstrated uses different to those recorded in ethnographic sources. The frequency and distribution of starch granules on different surfaces of the artifact, the presence of other plant microresidues such as phytoliths, and analyses of associated use-wear patterns are commonly used to support such functional interpretations. Associated sediment samples as well as laboratory consumables should be analyzed routinely for background starch to rule out post-depositional contamination of the artifacts (e.g., Nadel et al. 2012; Crowther et al. 2014).

Starch residues on tools used in food preparation or in sediments from such activity areas can give indirect clues about the role of plants in human diet. However, more direct dietary information can be gained by analyzing starches preserved in charred or desiccated food remains, dental calculus, stomach contents, coprolites, and cess pits. Dental calculus in particular has become a key source of evidence of early diet, including that of our hominin ancestors, owing to the long-term preservation potential of its mineralized composition (Henry et al. 2011). Another advantage of using this approach to reconstruct diet is that plant foods that can be eaten unprocessed (such as certain starchy fruits and nuts), and are therefore unlikely to leave traces on artifacts, may be detected in calculus or paleofecal remains. However, it is presently unclear how representative these remains are of past diet, owing to a variety of short- and long-term temporal biases and a still-poor understanding of the accumulation processes involved in the formation of calculus. Coprolites only reflect foods consumed in a short time prior to excretion by a single individual, whereas cess

deposits can reflect much longer time periods relating to multiple individuals. Starch granules recovered from food storage contexts (such as sediments from storage areas, pits, or bins, or in residues on storage vessels), and food discard (such as midden or refuse pits) may indicate the types of foods available for consumption. Evidence of plants used for medicinal and other nonfood purposes can be recovered from calculus and paleofecal sources.

Another area of study in which starch granule analysis has helped make significant advances is the origins and spread of agriculture. Starch granules have provided some of the earliest evidence for cultivated crops in tropical regions such as the New World Neotropics, Southeast Asia, and the Pacific, where many early crops are vegetative and often do not preserve well or produce other diagnostic remains. Studies are expanding in more temperate regions such as east and southwest Asia. Detailed reference collection analyses have focused on differentiating the starches of domesticated crops from those of their wild relatives based on subtle differences in the size and shape of the granules within a population. One of the best-studied examples is maize (*Zea mays*) (Holst, Moreno, and Piperno 2007) (see MAIZE). Another source of evidence for early agriculture comes from starch granules in sediments from agricultural features or on associated artifacts. Aspects of the production systems involved may be inferred based on landscape transformations and the agronomic requirements of the plants, as demonstrated at Kuk Swamp in the Papua New Guinea highlands (Denham et al. 2003), particularly in conjunction with ethnographic studies of traditional practices in the study region.

Despite being a relatively novel paleoethnobotanical method, starch granule analysis is rapidly growing in the scope of materials, time periods, and regions around the world to which it is being applied. The ongoing development of regionally specific reference collections and starch identification keys for economic taxa will continue to facilitate this expansion and provide new insights into past plant use, including in deep-time settings. Another aspect of starch granule analysis that is likely to see significant advances in future concerns molecular taphonomy. A better understanding of factors affecting the long-term preservation and diagenesis of

starch may resolve debates about the reliability of archaeological identifications and interpretations. More rigorous understanding of these issues, particularly through biomolecular studies, will ensure robust reconstructions of past relationships between people, plants, and the environment using this technique.

Taphonomy

KAREN B. BORRAZZO

Instituto Multidisciplinario de Historia y Ciencias
Humanas, CONICET, Argentina;
Universidad de Buenos Aires, Argentina

The term taphonomy (from the Greek words *taphos* meaning “burial” and *nomos* meaning “laws”) was originally selected by Russian scientist Ivan A. Efremov (1940) to name a specialization within paleontological research devoted to the *study of the transition of animal remains from the biosphere into the lithosphere*. Thus, it was conceived as the detailed study of the processes and transformations undergone by an organism from its death to the fossilization of its remains.

Although this definition of taphonomy primarily dealt with Efremov's interest in the passage of terrestrial vertebrate remains from the biosphere into the lithosphere, subsequent uses of this approach to study different fossil assemblages broadened its application to other organic remains (plants, molluscs) and beyond the paleontological record. Indeed, it was within the field of archaeofaunal studies (see ZOOARCHAEOLOGY) that most nonpaleontological theoretical and methodological contributions to taphonomic research took place. In recent decades, archaeologists began to develop and systematize taphonomic frameworks to study nonorganic materials, such as lithic artifacts, on a regular basis as well (Hiscock 1985). Although not without dissent, archaeological practitioners of bone taphonomy support the current expansion of taphonomic perspectives towards the analysis of other materials of the archaeological record (see ARCHAEOLOGICAL RECORD).

Taphonomy can be broadly defined today as the theoretical and methodological scientific approach devoted to understanding the post-depositional (taphonomic) history of any fossil record (paleontological, archaeological, forensic, or other), considering all its

components, their spatial arrangement, and context (Domínguez-Rodrigo, Fernández-López, and Alcalá 2011). It seeks to identify the mechanisms and the sequence of events involved in the formation of any assemblage and its sedimentary matrix. Furthermore, it studies the processes of preservation and how they affect information in the fossil record (Behrensmeier and Kidwell 1985). Thus, taphonomy addresses the constant tensions between preservational and destructive media through the study of the record of these tensions on different materials (Borrero 2014a).

There is increasing recognition of the fact that every fossil record has been affected by taphonomic processes and that the impact of those processes needs to be properly evaluated in order to proceed with paleobiological or behavioral interpretation (see INTERPRETATION). Indeed, a taphonomic diagnosis is key to assessing bias and adjusting research questions to the characteristics and scale of the record under study. Or the other way around: if a taphonomic research is conducted at the landscape or regional scale, it guarantees the selection of the more adequate loci to answer specific research questions (Borrero 2014b; Burger, Todd, and Burnett 2008). Thus, from a taphonomic perspective, the transformations undergone by material remains within the process of fossilization are not only biased but also an additional source of information. Certainly, the widespread integration of taphonomic approaches in archaeological studies proved that most archaeological sites are better explained as cumulative, time-averaging, and dynamic phenomena (i.e., palimpsests exhibiting differential integrity, resolution, and preservation) rather than static well-preserved “living floors.”

Several basic concepts are the backbone of taphonomic approaches. *Agents* are the sources of energy (e.g., wind) that trigger different *processes* (e.g., transport). The latter modify the properties of material remains; such changes are known as taphonomic *effects*. Finally, *taphonomic history* is the sequence or order in which agents and processes acted upon an assemblage (Gifford 1981; Lyman 1994).

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

© 2018 John Wiley & Sons, Inc. Published 2018 by John Wiley & Sons, Inc.

DOI: 10.1002/9781119188230.saseas0568

Each taphonomic agent (e.g., wind, water, gravity, fauna, vegetation) originates manifold taphonomic processes (e.g., transport, sandblasting, dissolution, trampling, gnawing), which comprise physical, chemical, or biological mechanisms. These mechanisms impinge on the original attributes of remains. Within taphonomic studies, processes and their effects are separated into two general realms according to the context—before or after burial—in which they take place. *Biostratinomy* is the segment of taphonomic history that spans between the death of an organism and the final burial of its remains, while fossil diagenesis (see *DIAGENESIS OF BONE*) comprises the modifications occurring on remains after burial. Thus, since weathering (the physical and chemical decay of bone components) mainly occurs in subaerial contexts, it falls within the realm of biostratinomy, while bone mineralization and deformation are primarily diagenetic processes.

More generally, taphonomic effects on any fossil remain can be classified into two basic categories: *morphological* and *distributional* alterations. The former includes changes in the aspect, texture, shape, size, and so on of elements. The meaning of morphological effects in terms of formational history can be evaluated at the individual level (e.g., on an isolated specimen), although an assemblage approach is more informative. Examples of morphological modifications on different raw materials (bone, lithic, ceramic, wood) include polish, abrasion, fractures, tooth marks, cracking, root etching, weathering rinds, and coatings. On the other hand, distributional modifications transform the spatial arrangement of fossil remains. These phenomena encompass the movement of specimens and changes in their position—such as vertical and horizontal displacements, changes in the axial orientation, inclination, and inversion. Burial also modifies the distributional properties of the assemblages. Unlike morphological modifications, the assessment of taphonomic spatial changes is only feasible at the assemblage level. The study of taphonomic effects is essential for assessing the existence of taphonomic bias in fossil assemblages and identifying its possible sources.

Several factors determine the occurrence and characteristics of taphonomic effects. First, each environmental, sedimentary *context* exposes assemblages to differential conditions (i.e.,

potential taphonomic agents and processes). Therefore, researchers need to build any taphonomic study on a case-specific basis: identify the past and present agents that were locally available, the energy and magnitude of the processes they triggered, their signatures on different materials, and so on. Second, taphonomic effects vary according to the *intrinsic properties* of each organic or nonorganic element (i.e., physical and chemical attributes of remains). Thus, material-specific frames of reference are required to undertake the taphonomic study of every component of a multifabric record, as is the case of many archaeological assemblages (bones and ivory (see *BONES AND IVORY*), lithic, ceramic, metal, wood, etc.). Third, it is expected that the intensity and extension of taphonomic effects vary according to the *duration* of the process. Furthermore, given the sequential and cumulative nature of taphonomic effects, earlier processes in the taphonomic history of an assemblage may facilitate the subsequent transformations of remains by a different mechanism.

Taphonomic methods integrate the principles, knowledge, and case studies from natural sciences (biology, physics, chemistry, geology) with observations on the fossil record itself. Actualism is also central to most taphonomic research. Uniformitarianism principles, modern experiments (see *EXPERIMENT IN ARCHAEOLOGY*), and naturalistic observations provide jointly with natural sciences the frame of reference to assess taphonomically the patterns exhibited by the fossil record (e.g., Weigelt [1927] 1989). Hypothesis testing (see *HYPOTHESIS TESTING*) and the integration of data provided by other lines of evidence are common procedures in taphonomic research, since more than one agent and/or process produces the same trace or effect on material remains (equifinality). Therefore, competitive explanations are evaluated against a corpus of actualistic and fossil data to account for fossil trends.

The general goals of taphonomic studies within the realms of archaeological research have mostly focused on:

- assessing differential attrition to reconstruct the original content and patterns of material remains (see *DETERIORATION*);
- establishing agents of accumulation and modification as well as the sources of bias;

- detecting and describing common taphonomic trends at different spatial scales, whether to recognize background noise (e.g., the natural deposition of bones or taphonomic “bone rain,” geofacts or other lithic pseudoartifacts) or to identify sites or spaces that share their taphonomic properties (*isotaphonomy*);
- characterizing the taphonomic history of a fossil assemblage, that is, detailing the circumstances (sequence of events) under which the assemblage existed through time.

Taphonomy has become a powerful and necessary tool for disciplines dealing with the fossil record. Current research suggests that the incorporation of a taphonomic perspective improves the understanding of the sources of variation for every component of archaeological assemblages. Finally yet importantly, a widespread integration of taphonomy in cultural and natural resource management is highly beneficial for improving conservation policies and sustainable practices worldwide.

Temperate Environments

CATHERINE BARNETT and
NICHOLAS BRANCH
University of Reading, UK

Temperate environments today comprise two global zones between the polar regions and Tropics of Capricorn and Cancer. However, to account for changes in time and space, here we define them as areas characterized by a common climate, with cool winters, warm summers, substantial precipitation, and consequently relatively stable ecosystems. They may have existed in parts of what are now equatorial regions during past glacial periods, but temperate environments are predominantly a feature of warm interglacial periods, which have periodically interrupted the generally cold conditions of the Quaternary period from ca. 2.6 Ma to the present.

There is only fragmentary evidence for older, pre-Holocene temperate (interglacial) environments. Subsequent glaciations and recent geomorphological processes, such as coastal erosion, colluviation, and alluviation, have removed sedimentary deposits containing fossilized remains of plants, animals, and cultural remains. Some of the best-surviving examples spanning the Late Quaternary (ca. nine interglacials in the last 650 kya BP) occur in Europe; for example, the Thames Valley terraces provide an extraordinary sequence of riverine deposits that have enabled reconstruction of the variable climate and environment. During Marine Isotope Stage (MIS)-11 at ca. 400 kya BP, their terrestrial biostratigraphic record indicates oak, alder, and hazel woodland with a fauna quite unlike today, including deer, horse, and bison, and extinct giant ox and giant deer, mixed with fauna representing a savannah-like environment, notably straight-tusked elephant, rhinoceros, and lion (e.g., Swanscombe). Elsewhere, lake sediments

provide complementary evidence of terrestrial and aquatic flora and fauna (e.g., Marks Tey). The last interglacial (MIS-5) experienced higher temperatures, more widespread tropical conditions, and higher global sea levels, but still offered greater prospects for floral and faunal expansion into areas uninhabitable during glacial periods.

Cycles of change can be recognized (Figure 1), with rapid warming events at the end of glaciations, followed by large-scale remodeling of continents due to sea-level rise (see SEA-LEVEL CHANGE), and in some areas land depression adding to flooding (see FLOODING) by marine transgression of vast expanses of land. Subsequent rebound has re-exposed some of these areas, making them progressively available for terrestrial life. Evolution of post-glacial landscapes occurred in terms of hydrology, landforms, recolonization of thermophilous species, vegetation succession, soil maturation, and faunal migration before decline occurred with progressive cooling, leading into the next glacial period. The cycle of appearance and decline is presumed relatively short, with MIS-11 lasting ca. 40,000 years.

The investigation of the Holocene (MIS-1), starting at ca. 11.7 kya BP, and previous interglacials relies on a multiproxy approach and the integration of numerous datasets. Temperate conditions show in the geomorphological and sedimentary record as fine-grained alluvial and estuarine deposits laid down by meandering river systems (see RIVER SYSTEMS), accumulations of organic layers and peats in marsh areas, and development of stable weathered soil horizons in drier terrestrial areas. This is in contrast to glacial-age deposits, typified on land by coarse unsorted river gravels and scree laid down by higher energy unstable conditions in an open, poorly vegetated environment (see GLACIAL AND PERIGLACIAL ENVIRONMENTS). The biostratigraphic record provides direct but fragmentary evidence of profound plant and animal responses to these major climatic and landscape changes.

Figure 1 Environmental responses to Quaternary climate change.

Source: Republished with permission of Elsevier from Shreeve and Branch, 2010, "A Quaternary Timeline: A Teaching Tool for Interpreting Palaeoenvironmental, Palaeoclimatic and Archaeological Change over the Last 500,000 Years." *Proceedings of the Geologists' Association* 121: 83–86.

Holocene warming has not been linear or synchronous globally, with a series of minor climatic downturns and wetter (pluvial) periods identified through paleoecological and, more recently, documentary sources. A downturn at 8.2 kya BP has been suggested (Mayewski et al. 1997) and a Medieval Warm Period proposed for the tenth to fourteenth centuries CE, succeeded by the Little Ice Age from the fourteenth to nineteenth centuries, with a demonstrable effect on agriculture, settlement patterns, and society. For example, in Greenland and Iceland, expanding sea ice caused a shift in diet from agricultural to wild, and abandonment of marginal areas. Biostratigraphic data and accelerated sand dune formation indicate a Holocene thermal maximum at ca. 6.5 kya BP in North America, followed by a trend of cooling and wetness with the Neoglacial period beginning at ca. 4 kya BP, as supported by data from the Greenland ice core datasets.

Techniques used to study temperate environments

Holocene deposits provide information on landscape formation and modification, human economies, and subsistence. Their study highlights the challenges and complexities of regional climate and environmental reconstructions based on multiproxy records. The potential lines of investigation are manifold and constantly developing, with the following principal techniques used in isolation or combination to provide complementary information on any given aspect of reconstruction:

- Geoarchaeology (see GEOARCHAEOLOGY) helps identify areas of heightened potential for past human settlement, areas of human impact on the landscape, activity areas within sites, and route ways and sets a framework and

taphonomic context for paleoenvironmental and archaeological remains.

- Paleoenvironmental studies including paleoethnobotany (see PALEOETHNOBOTANY) contribute to reconstruction of landscape, human management, and exploitation of plant resources, including aspects of agriculture and diet (see VEGETATION MODELING USING POLLEN DATA).
- Zooarchaeology (see ZOOARCHAEOLOGY) provides data on past populations, including health, diet, disease, and privation, as well as species viability, adaptation, livestock breeding, management, and husbandry. The study of past insect, foraminifera, ostracod, and mollusc assemblages is useful in the reconstruction of local terrestrial and aquatic environments.
- Scientific dating methods such as radiocarbon dating, optically stimulated luminescence (OSL), uranium-series, and thermoluminescence (TL) techniques provide chronological control to the sedimentary and biostratigraphic records of human activity.
- Spatial and imaging techniques include use of light detection and ranging (LiDAR), infrared, and aerial photo interpretation, often managed within geographic information systems (GIS), to map past landforms, paleochannels, former coastlines, archaeological features, and monuments.

Major themes

Temperate environments are of key interest in the context of human lifeways, habitation, and migration because they offer a hospitable climate, and varied, relatively plentiful, plant and animal resources. Their study is of particular resonance given the global challenges and debate surrounding recent climate change and its triggers, drivers, timing, environmental consequences, and sustainability for humankind. The current emphasis in archaeological science is therefore on what the study of past temperate environments can teach us about dynamic change and adaptive strategies for plants, animals, and humans in the future. Key themes include the anthropogenic impact on the landscape through hunting, deforestation,

agriculture, urbanization, and interaction with climate change.

Biological responses to deglaciation inside and beyond the extensive glaciated zone were profound, but varied in timing, nature, and type. The spread of thermophilous plants is of interest. Pollen records from temperate southern South America indicate a vegetation response to widespread warming; for example, the expansion of *Nothofagus* forest in Tierra del Fuego (Rabassa et al. 2000). In northwest Europe, early recolonizers of open landscapes, such as birch and aspen, expand first in the archaeobotanical record, followed by encroachment of pine, alder, and then hazel within 500 years of the start of the Holocene. Denser deciduous forests followed, with significant impact on faunal populations, which shifted northwards. This had major consequences for human subsistence and settlement in an increasingly closed landscape with a changing resource base, and led to a series of responses including progressive changes in tool technology and the start of environmental control and clearance through burning from the Early Mesolithic period at ca. 11 kya cal BP onwards (e.g., Barnett 2009) (see ENVIRONMENTAL MANAGEMENT WITH FIRE). Dated fossil floral and faunal remains and biomolecular and genetic data suggest that Mediterranean areas with a southerly aspect—for example, southern France (Dordogne), Spain, and the European peninsulas—acted as glacial refugia, havens for warm-loving flora and fauna from which they could re-expand once climatic amelioration had begun (Tzedakis et al. 2003).

The timing of human arrival in the Americas is controversial, but dated remains associated with the pre-Clovis Miller complex lithic assemblage from Meadowcroft rock shelter, Pennsylvania indicate from at least 16 kya BP (Adovasio and Page 2002). A potential impact of this early colonization was the widespread extinction of megafauna, its timing first coincident with the end of the glacial period but also perhaps associated with overhunting by new arrivals, and most recently bison disappearance at the time of European colonization. There may have been a direct causal relationship or a more complex one related to land pressure, disease, and competition.

Dating of domesticates indicates that Neolithic agriculture arrived in the Mediterranean with a major human dispersal from Anatolia during

the Early Holocene at ca. 8.5 kya BP. However, recent DNA evidence suggests expansion from a Near-Eastern refuge as early as the Late Glacial at ca. 13 kya BP (Pereira et al. 2017), triggered by climate change and supported then by a hunter-gatherer lifestyle. The spread and adoption of agriculture and associated large-scale deforestation and habitat change of the Neolithic and Bronze Age periods are indicated by the appearance of domesticates, weeds, and more widespread grass and heathland habitats in the bioarchaeological record from ca. 6 kya BP in northwest Europe.

A period of Mid-Holocene rapid climate change from 6 to 5 kya BP in the Americas coincides with evidence for abandonment of sites (e.g., Atacama, Chile), continuous occupation (e.g., Catamarca, Argentina), and changes in subsistence practices—for instance, in food-gathering practices and exploitation of a wider range of environments to cope with increased aridity, for example grinding of wild *Prosopis* sp., *Schinus* sp., and *Geoffroea* sp. on the plains and/or piedmont of Mendoza, Argentina (García 2005). Arable and pastoral farming practice from historic times onwards has led to profound landscape changes in North America, notably in the Mid-West, where establishment of grassland prairies and areas of desertification has been recorded on a century-scale. Debate continues on whether agricultural and industrial developments over this period have had a significant impact on the course of current and future climate change.

Challenges and constraints

Key constraints to the study of temperate environments include a lack of suitable preservation environments, and their progressive degradation due to the impact of development, agriculture, and aggregate extraction. Loss of opportunity for recovery of suitable remains can occur through other natural or quasi-natural processes such as erosion, landslip, fluvial scour, and deep burial, causing problems of visibility and changing patterns of key depositional and preservational environments, such as the shift in arid versus maritime zones. The rate or patterns of these may increase with future global climate change, whatever its driver. Potential mitigation includes

targeted hydrological and ecological management of areas of waterlogged and marginal areas of known research potential, and designation and protection of key archaeological sites.

Chronological control can be problematic; also lack of funding for archaeology and archaeological science, lack of capacity and skills shortages due to a decline in those studying the subject at degree level, and a poor planning framework in many countries can lead to lack of adequate prospection, excavation, sampling, and mitigation against development or extraction and for the post-excavation analysis process to be minimized or lost.

Future directions

Further development of the fields of study and techniques described will continue to evolve and open up new opportunities for studying past environments and human-landscape relationships. In terms of understanding and adapting to future climate change, early prehistory (terminal Late Glacial to Early Holocene, equating to the Upper-Paleolithic to Mesolithic periods in most temperate zones) is seen as being of key importance in looking at ecological and human responses to major climatic transitions. The application of archaeological techniques to post-industrialization human impact on the environment (the Anthropocene) may become increasingly important in understanding feedback systems and habitat response to change.

Tephra and Volcanic Ash Analysis

ANTHONY J. NEWTON

School of GeoSciences, University of Edinburgh, UK

Volcanic ash (tephra) layers provide an invaluable record of volcanic activity and its impact on the environment. Tephra layers are widely used in archaeological research to provide chronological frameworks in extensive areas downwind of major volcanic zones throughout the world. Archaeological applications of tephrochronology range across all periods of human evolution, from the earliest Pliocene hominids in the Afar region of Ethiopia through to modern times.

The Icelandic geoscientist, Sigurdur Thórarinnsson (1944) established the terminology and principles of tephra studies and tephrochronology, and used the classical Greek word tephra (τεφρα) to define all pyroclastics (solid material produced by an eruption) erupted into the atmosphere, irrespective of particle size, shape, or composition. Tephrochronology originally described the use of tephra layers to correlate sediment sequences, but now includes all aspects of tephra studies, and a person who studies this is called a tephrochronologist. Tephra is produced from the fragmenting of magma in an explosive volcanic eruption. Tephra layers can range in thickness from several meters close to the source, to invisible cryptotephra consisting of a few grains per cm³ in distal areas.

Tephra isochrons

A primary airfall tephra layer is formed in a geological instant (usually days, or at most weeks) and so reflects a discrete and short-lived moment in time. If the tephra layer can be followed spatially, identified and correlated between sites, it becomes an isochron. The base of the tephra layer represents a comparable moment in time

wherever that isochron occurs. The unambiguous identification of an isochron allows its date to be transferred to every location where it is found. This can be crucial when trying to establish correlations, synchronicity between, or the order of, events. This ability to carry dates to new locations means that tephra layers can provide an independent means of checking other dating techniques (see DATING IN ARCHAEOLOGY).

The archaeological significance of tephrochronological isochrons is demonstrated in Iceland and New Zealand by distinctive tephra layers which are coincident with the arrival of people. Iceland was settled in the mid to late ninth century AD and based on medieval written records derived from oral history; the traditional date given for this is 874 CE. Archaeological research has shown that the settlement of Iceland is coincident with a distinctive two-colored tephra layer, consisting of a white lower component, sourced from the Torfajökull volcanic system, and a much more widespread upper olive green tephra, erupted from the Veiðivötn volcanic system. This tephra layer, often termed the “Settlement Layer” or the Landnám Tephra Layer (LTL), provides a widespread isochronous marker in soil, peat, and lake sediments, which essentially divides an Icelandic environment without people below the layer, to the one above, where the impact of human settlement can be studied. The LTL is found in Greenland ice cores and is dated to around 877 CE (Schmid et al. 2017).

The dating of the settlement of the New Zealand archipelago has been controversial, with older dates based on radiocarbon analysis being at odds with numerous other evidence for the arrival of people some 700 years ago. Tephrochronology has played a major role in resolving this debate, with the recognition that the distinctive white Kaharoa Tephra (1314 ± 12 CE; Hogg et al. 2003) in the eastern and northern part of the North Island is found below all of the reliable archaeological and paleoenvironmental evidence for the arrival of people.

Tephrochronology relies on the Law of Superposition, where younger sediments are deposited

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

© 2018 John Wiley & Sons, Inc. Published 2018 by John Wiley & Sons, Inc.

DOI: 10.1002/9781119188230.saseas0571

sequentially over older ones. Establishing the stratigraphic relationships of tephra layers is termed tephrostratigraphy. Tephrochronology, wherever it is applied, relies on identification, correlation, and dating of tephra layers. In terrestrial sequences, the tephra layers occur in soils, lake sediments, peats, glaciers, and even in archaeological deposits.

The physical properties of macroscopic tephra layers play an important part in the characterization of a layer. The chemistry of the magma is responsible for the color of the glass and mineral components and therefore the color of the tephra layer. Particle size of a tephra layer will decrease with distance from the volcano and away from the main axis of fallout, and can be semi-quantitatively assessed by describing the tephra as “fine, medium or coarse,” or can be measured quantitatively by sieving or using a particle size analyzer.

Archeologists can also utilize less than “ideal,” disturbed tephrostratigraphies. Dugmore and Newton (2012) state that “total tephrochronology” includes disturbed or missing tephra layers, or layers that show evidence of reworking, in order to fully understand a landscape at the time of tephra deposition. Environmental archaeological research benefits from the better understanding of vegetation cover, landscape disturbance, erosion and human impacts that these less than “perfect” layers provide.

Some volcanic eruptions, either submarine or ones close enough to a coast, can produce large (cobble-grade) fragments of pumice, which can float on water and be transported thousands of kilometers by wind and ocean currents. For example, multiple Holocene eruptions from the Katla Volcanic System, southern Iceland, have produced pumice which ocean circulation has spread around the North Atlantic basin from North America to NW Europe. The pumice is found in coastal archaeological sites in Arctic Canada, Greenland, the British Isles, Scandinavia, and Iceland. Some of this pumice was used as an abrasive tool for smoothing wood, antler, bone and animal hides and as fishing floats. Thus, pumice can form part of the artifactual record of past human societies, as well as contributing to site chronology.

Cryptotephra

Traditional tephrochronology uses visible tephra layers in areas close to volcanic activity, such as in Iceland, Japan, New Zealand, Central America, and Alaska. However, it has long been known that tephra from eruptions can travel great distances. As early as the 1960s, tephra layers were identified from Atlantic sediment cores and from peats in Scandinavia. The work of Dugmore (1989) and coworkers in the late 1980s clearly established that Icelandic tephra layers occur in Scottish peat deposits. They also recognized their potential in paleoenvironmental and archaeological research (see PALEOENVIRONMENTAL RECONSTRUCTION). These far-travelled tephra are not visible to the naked eye, and so the term cryptotephrochronology is used to signify that the layer is hidden (Davies 2015). Cryptotephra can occur in peats, organic silts, lake sediments, ice cores, and even cave deposits and rock shelters. The number of shards per gram may vary from many thousands to less than 10 shards per cm³, with particle sizes usually less than 125 microns and as small as a few microns.

As cryptotephra layers are not visible to the naked eye, a variety of techniques are required to detect them. X-radiography and magnetic susceptibility, combined with XRF core-scanning, can be used. Incineration can isolate tephra grains from organic material, while mineral acid digestion can also remove organic matter. Where the tephra are mixed with high concentrations of inorganic material, density separation/flotation techniques utilizing liquids of specific densities are employed. Sieving can also increase the concentration of fine-grained cryptotephra.

Once isolated, the tephra grains are then generally mounted on a microscope slide and counted under an optical microscope. The isotropic property of volcanic glass shards helps to differentiate volcanic glass from other detrital material, such as quartz. Volcanic glass shards can also have a distinctive appearance ranging from platy to pumiceous, with numerous vesicles. These morphological characteristics help to differentiate the glass shard fraction of a tephra layer from other detrital mineral material. Characteristic volcanic minerals may also be present.

Cryptotephrochronology is widely used in archaeologically related paleoenvironmental studies, particularly in wetlands. In the British Isles, numerous tephra layers occur in Holocene peatlands, especially in Ireland and Scotland, and are routinely used in constructing chronological frameworks in studies of landscape change, human impact, and human–environment interactions. Although mainly sourced from Iceland, Alaskan tephras are also present. Other examples include the 39 ka Campanian Ignimbrite tephra, which has proved to be an invaluable isochronous marker horizon across southeastern Europe at the time of the Middle to Upper Paleolithic transition, and the late glacial Laacher See tephra, an important Allerød isochron in northern Europe.

Dating

Dating of tephra layers depends on the age of the tephra and its context. Depending on context, Late Quaternary and younger tephras are dated by a range of methods including written records, radiocarbon dating of associated organic matter, linkage to dendrochronology, or by the presence of the tephra layers in incremental records such as ice cores or varved sediments (see VARVE CHRONOLOGY).

Written records give the most accurate and precise calibration method. In Iceland, an excellent post-settlement historical record of volcanic activity exists. This has allowed the development of a robust and high-resolution tephrochronological framework, utilized routinely by archaeologists.

Although radiocarbon dating of tephra layers is common, tephras also provide an independent check of radiocarbon dates. The isochronous nature of tephra layers means that an accurate and precise date is transferred to anywhere that tephra is found. Tephras dated by historical records, radiocarbon dating, or ice core ages can also be an integral and valuable part of Bayesian dating frameworks.

Ar–Ar dating (see ARGON–ARGON DATING) is the most common means of directly dating tephra layers. For example, the massive Younger Toba Tuff (YTT) is dated from Middle Paleolithic

archaeological sites in India to 75.0 ± 0.9 ka (Mark et al. 2014).

Tephra geochemical analysis

It is preferable to analyze individual tephra grains, and in many cases the glass fraction is studied. A smooth cross-section of the tephra grains is required for geochemical analysis, and tephra samples are incorporated with resin either into a block or onto a microscope slide, and ground and polished to create a smooth cross-section of the tephra grains.

Major and minor element oxide abundances are frequently acquired using electron microprobe analysis (EMPA). An electron microprobe is a dedicated instrument designed to obtain quantitative geochemical analyses using wavelength dispersive spectrometry (WDS), but it is also possible to use a detector using energy dispersive spectrometry (EDS) attached to a scanning electron microscope (SEM). The former is preferable for accuracy and precision, while the latter is faster and cheaper and sometimes the only means of analyzing the smallest tephra shards.

Major and minor element geochemistry is not always able to discriminate between tephra layers from the same source, but trace element abundances often can. Laser ablation inductively coupled plasma mass spectrometry (LA-ICP-MS) is most frequently used to obtain trace element concentrations, and uses a fine resolution laser (as small as a few microns in diameter) to ablate material from a tephra grain, which is ionized and measured in a mass spectrometer.

Testate Amoeba Analysis

EDWARD A. D. MITCHELL

University of Neuchâtel, Switzerland; Botanical
Garden of Neuchâtel, Switzerland

RICHARD PAYNE

University of York, UK; Penza State University, Russia

What are testate amoebae?

Testate amoebae are a group of amoebae that produce a shell (called a “test;” Figure 1). These organisms have also been referred to as shelled amoebae, testaceans, arcellaceans, or rhizopods, but these terms are now not preferred. Testate amoebae belong to at least three unrelated groups of organisms: Euglyphida, Arcellinida, and Amphitrematidae. However, for application in bioindication, paleoecology, and archaeology, these three groups are generally treated together as they play similar functional roles and produce decay-resistant shells of similar size ranges (mostly ca. 20–150 μm). Testate amoebae are mostly heterotrophic organisms feeding on bacteria, fungi, other protozoa, microalgae, and in some cases even microscopic animals such as nematodes and rotifers. A few species, living in either acidic *Sphagnum* peatlands or lakes, bear symbiotic algae and are thus also photosynthetic. Testate amoebae are common in lakes, rivers, peatlands, and soil, and to a lesser extent in brackish water. They are quite diverse: ca. 2,000–3,000 species have been described, but recent molecular studies are revealing a wealth of hidden diversity.

Applications of testate amoeba analysis in paleoecology

Different testate amoeba species have different environmental preferences and the shells of testate amoebae allow species identification even after the organism is dead, thus making it possible to use them to infer past

environmental conditions (Charman 2001). The most widespread applications of testate amoebae have been for the reconstruction of the past wetness of peatland sites (see PEAT DEPOSITS) as a proxy for hydroclimate. Other applications involve the reconstruction of sea-level change (see SEA-LEVEL CHANGE) from coastal sediments and aquatic pollution (see WATER POLLUTION) from lakes (see LAKE DEPOSITS).

Not all shell types preserve equally and such taphonomic bias should be understood when using these organisms in paleoecology or archaeology (Mitchell, Payne, and Lamentowicz 2008; Wilmschurst, Wiser, and Charman 2003). The shells of genus *Euglypha* (Figure 1a) and related euglyphids are the most fragile. These shells are constructed of delicate siliceous plates and are typically only found in optimal depositional conditions (Payne 2007; Swindles and Roe 2007). By contrast, the shells of genus *Assulina* (Figure 1i), which are also made of siliceous scales but overlain by an organic coating, are among the most resistant of all testate amoebae. Taxa producing proteinaceous shells (e.g., *Hyalosphenia*, *Arcella*) are usually very resistant (Mitchell et al. 2008).

The preparation of samples for testate amoeba analysis depends to some extent on the substrate type, but generally requires wet sieving to remove the coarse material (usually $>150\ \mu\text{m}$). Some methods also recommend subsequent sieving to remove fine material (usually $<15\text{--}20\ \mu\text{m}$), retaining the intermediate fraction (e.g., $15\text{--}150\ \mu\text{m}$). Some very small species (e.g., *Trinema lineare*) can be lost when using fine sieving, but the big advantage of this step is that it removes fine sediment, which can make up a substantial proportion of the substrate in some contexts. Smaller species may, however, be ecologically meaningful and by using this sieving method loss of useful information can occur (Payne 2009). Slides are prepared for microscopy using a mounting medium such as glycerol and inspected at magnifications typically of 2–400 X. The number of shells to be counted depends on the degree of precision of ecological information

Figure 1 Some of the diverse range of testate amoebae identified in paleoecological and archaeological studies. (a) *Euglypha ciliata*-type; (b) *Nebela tinctoria*-type; (c) *Arcella discoides*-type; (d) *Centropyxis aerophila*-type; (e) *Diffugia oblonga* (PenardCollection, Natural History Museum of Geneva, Image from Wikimedia commons, https://commons.wikimedia.org/wiki/File:Collection_P%C3%A9nard_MHNG_demo_sample.tif); (f) *Trinema enchelys*-type; (g) *Cyclopyxis kahli*; (h) *Trigonopyxis arcula*; (i) *Assulina muscorum*. Scale bars: a, b, d, and e, 20 µm; c, f, g, and h, 50 µm (10 µm per increment); i, 10 µm.

required. The general goal is to count 150 shells, but it has been suggested that lower numbers, for example, 50, can provide useful ecological information (Payne and Mitchell 2009). If rare species are considered useful then their presence and abundance can only be estimated using much higher counts. The use of contrast-enhancing microscopy such as phase contrast or differential

interference contrast is very useful to spot and identify transparent species such as the genera *Euglypha*, *Trinema*, and *Corythion*. There is unfortunately no single up-to-date and user-friendly identification guide to testate amoebae. Many references are either out of date or focus solely on a small number of species, and guides are published in many languages.

Applications of testate amoeba analysis in archaeology

The application of testate amoeba analysis is currently well established in paleoecology but less so within archaeology. Despite generally limited application, there are several situations where testate amoeba analysis has the potential to make a substantive contribution to archaeological research. The first of these is through the role of testate amoebae as a proxy for the reconstruction of past climate change. Testing hypotheses regarding the role of climate in driving human social and cultural change often requires an understanding of climate change at a local and regional scale. Paleoclimate reconstructions using testate amoebae can help provide this information. Sites with paleoecological potential for testate amoeba studies are relatively widespread in the temperate and boreal zone, often allowing climate reconstructions in the vicinity of archaeological sites of particular interest. An example of this is for understanding apparent Bronze Age depopulation of the uplands of southwest England. Amesbury et al. (2008) used testate amoeba analysis to understand regional climatic change, proposing evidence for a climatic deterioration (ca. 1150–1400 cal. BCE) and drawing linkages with the established archaeological record. Used in combination with other methods, testate amoeba analysis has the potential to help untangle the complex links between environmental change and changing human societies.

Within the context of archaeological sites themselves, testate amoebae have been most widely used in wetland archaeology. In wetland sediments, testate amoeba shells are often well preserved, offering potential as indicators of past environmental conditions. For instance, Gearey and Caseldine (2006) applied testate amoeba analysis to a multiphase archaeological site in southern Ireland to reconstruct change in peatland surface wetness. Their results suggested a long-term correlation between archaeological usage and wetness, with more construction of features such as trackways in drier phases of the bog's history. This is information that would be difficult to obtain by any other means. A related potential application could be to understand human impacts on peatland environments. For

instance, it is probable that many water-table drawdown events recorded in paleoecological records may represent human activities such as peat cutting or drainage. While this research direction has yet to be explored in detail, it is probable that testate amoeba analysis could cast light on human exploitation of wetland environments. Similarly, there is the potential for testate amoeba analysis to provide contextual information regarding archaeological artifacts found preserved in peat. A particular example of this is the bog bodies that have been widely found preserved in peatlands across northwest Europe. Plunkett et al. (2009) discuss the use of testate amoeba analysis as part of a multiproxy approach to understand the depositional environment of such a bog body in central Ireland. Their results showed that the depositional environment of the find was most likely a shallow pool. Testate amoebae may be recovered from a broad range of archaeological samples. There is a single record of testate amoeba analysis from an Egyptian mummy (Chardez and Lambert 1988). Fourteen testate amoeba tests belonging to five species (*Centropyxis aerophila*, *Plagiopyxis callida*, *Plagiopyxis declivis*, *Phryganella acropodia*, and *Nebela parvula*) were recovered from three dust samples. These species are frequently reported from soils and the morphology of these ancient specimens was indistinguishable from modern taxa. Such studies may allow insights into the life history and depositional environments of such artifacts.

A final use of testate amoeba analysis is as part of a wider suite of non-pollen palynomorphs (NPPs). Many testate amoeba shells are destroyed by the chemical treatments required in preparing samples for pollen analysis. However, some of the most robust tests, such as those of *Arcella* and *Archerella*, can survive and be encountered in pollen slides. An increasing proportion of palynological studies are aiming to quantify the diverse range of NPPs found in such samples, including testate amoebae. Payne et al. (2012) reviewed this literature and identified more than 50 palynological studies that had included testate amoebae, with several of these from archaeological contexts. While testate amoebae were not the focus of these studies, many nevertheless found that identifying testate amoebae yielded useful additional information. While pollen preparation methods

cannot be recommended for studies specifically aiming to quantify testate amoebae, the enumeration of testate amoebae in pollen-focused studies is a sensible approach, as the most abundant taxa are easily identifiable and provide useful contextual information (Payne et al. 2012).

It is clear that testate amoeba analysis has a great deal to contribute to archaeology, particularly in the wetland environments where testate amoebae are most abundant. This potential has currently only been exploited to a limited degree and much more could be achieved.

Urban Environments

MAŁGORZATA LATAŁOWA

University of Gdańsk, Poland

The rise of towns and cities was one of the most important developments of humankind. It not only was a major step in social evolution but also led to great changes in people's living conditions. Urban areas developed in different periods of prehistory and in historical times, in different geographic and climate locations, on lands with specific geomorphological conditions, and with specific opportunities and constraints, such as the availability of natural resources. The size and structure of the built environment also varied. Cities developed from different roots, such as military bases, seats of political power, religious centers, or centers of trade, craft, and industry. Despite these differences, urban areas have some distinct common features. Because they bring many people together, the land is densely built-up and supports some common arrangements and structures. Most of the population is not engaged in agriculture, so the main sources of food are grown in surrounding rural areas or are imported from further afield. Populations living in cities tend to be clearly structured according to social and economic status and occupation. Living in large centers generates specialized economic activities that in the past were clearly assigned to specific urban areas (e.g., markets, manufacturing areas, services). Densely populated and intensively built-up land influences local climate, and hydrological and biogeochemical cycles in different ways, and results in nutrient enrichment, and air (see AIR POLLUTION) and water pollution (see WATER POLLUTION). Such areas also support specific flora and fauna. All the above factors are important variables when studying the past urban environments from remains found in archaeological sites.

Both archaeology and natural sciences are developing our knowledge of how the urban areas of the past grew and functioned. The results

obtained concerning the natural environment are dependent on both the preservation of urban strata and understanding the sources and taphonomy of the remains recovered. Urban sites have usually been occupied for hundreds or even thousands of years. As a consequence, thick deposits with dense, complex stratification occur. In multiperiod sites, the older strata are frequently destroyed and truncated by younger structures, and different items may be redeposited as a result of human activity or natural processes. In contrast to archaeological artifacts which may be more or less definitively assigned to particular periods based on their typology, biofacts cannot be dated based on their form or type; direct dating by radiometric means is required. Therefore, well-sealed, closely dated stratigraphy is a basic prerequisite for the investigation of animal and plant assemblages, as well as for other traces of past environments. The taphonomy (see TAPHONOMY) of the subfossil assemblages of different groups of organisms in urban sites is especially complex and diverse, as it depends on both biological factors, such as the biology of the species being studied (e.g., diaspore productivity) and the resistance of their tissues to decay (see DIAGENESIS OF BONE and FORMATION PROCESSES), and the types of archaeological features and specific depositional processes at the site. The means of preservation (waterlogging, carbonization, mineralization, desiccation) have specific selective effects which have to be considered when interpreting both qualitative and quantitative data. Multiproxy studies provide the best means of diminishing the negative effects of the loss of information on past environments resulting from fragmentary preservation of the subfossil assemblages and biases of particular data types. By combining different methods it is possible to fill at least some gaps in a paleoenvironmental record.

There is a long tradition of the use of paleobotanical methods (see PALEOETHNOBOTANY) not only to gain knowledge on plant use, but also to reconstruct past urban environments. This is based on an assumption that the composition of wild flora depends on a number of

natural and cultural factors. The most thorough reconstructions of the urban flora and vegetation are made through the analysis of waterlogged fruits and seeds, which usually occur in great abundance and variety. Plants and plant communities are first and foremost perfect indicators of the whole range of soil and hydrological conditions and land-use. Using the ecological characters of plant taxa (e.g., the ecological numbers by Ellenberg et al. 1992), it is possible to define features of past habitats and to trace their transformation through time. Such reconstructions may concern specific locations within the urban space and are usually based on the results of analysis of a series of archaeobotanical samples from a site. It has been shown also that if the dataset is large enough, plant remains dispersed in unspecific cultural layers in different parts of an urban area can be used to detect even discrete changes in the ecological conditions (Latałowa, Badura, and Jarosińska 2003).

Pollen analysis (see PALYNOLOGY) of urban strata (on-site data) also has great potential for reconstructing the local natural environment, especially if non-pollen palynomorphs (NPPs), which include fungal spores, some algae, and cyanobacteria, elements of protozoans and invertebrates, are considered. This group of microfossils is invaluable in supplementing information on the local ecological conditions and some kinds of human activity, providing information on the vegetation of a site as well as presence of, for example, hay, fodder, or animal dung.

Where naturally infilling lakes (see LAKE DEPOSITS) and peat deposits (see PEAT DEPOSITS) are found within an urban area or its neighborhood (off-site data), pollen analysis can provide information on extra-local vegetation and the environment outside a town. As the areas around cities were a source of the raw materials and were used for food production, urbanization contributed to their transformation. Off-site pollen analysis can be used to detect these changes, such as the rate of deforestation, changes in forest composition, and agricultural practices.

Irrespective of period and geographical factors, the rise of any city leads to environmental change. In a growing city, patches of natural and seminatural vegetation gradually shrink, and are replaced by anthropogenic plant communities, often one

of lower taxonomic diversity and dominated by cosmopolitan species. Particularly, typical urban vegetation includes nitrophilous communities that grow on strips of ground beside buildings and moats, or near latrines or concentrations of waste. Also, vegetation typical of trampling places (pathways, streets) and disturbed soil are usually fairly common in urban sites. Gardens within urban areas are used mainly for growing vegetables, herbs, ornamental plants, and fruit trees and provide habitats for weeds. Gardening and transportation of imported goods into the town are the main routes for the introduction of alien species. Therefore, urban areas were, since their very beginnings, centers for synantropization of flora, reflecting the dynamics of long-distance trade and cultural contacts. Urban faunas are also distinct. A number of studies have demonstrated a clear relationship between faunal assemblages, the structure of a town, and an advancement of the urbanization process. Zooarchaeological studies (see ZOOARCHAEOLOGY) undertaken for the purpose of paleoenvironmental reconstruction of urban sites are based mainly on analyses of insect and microvertebrate remains. The structure of microvertebrate populations within urban environments is dependent on the arrangement of an urban space, such as density of buildings, presence of green areas, and methods of food storage. For example, in the densely built ancient cities of the Near East, more than 2,500 years ago, species-poor communities of small mammals (dominated by the house mouse *Mus musculus domesticus*) developed that are similar to those found in the densely populated core areas of modern cities (Weissbrod et al. 2014). Insect assemblages studied in different features and contexts within an urban site can show the relative abundance of both indoor and outdoor habitats and may illustrate, for instance, hygienic conditions, presence of grain pests, or an abundance of rotting matter. Different aspects of assemblages of various groups of insects in urban environments have been discussed by Kenward and Allison (1994).

Geoarchaeology (see GEOARCHAEOLOGY) is another important, but still not widely used, source of data on past urban environments. By using micromorphology (see MICROARCHAEOLOGY) to study deposits exposed in archaeological excavations it is possible to reconstruct modes

of formation of stratigraphic sequences in great detail and assess the character of the in-situ human activities and natural events that have produced these deposits. This method is still useful even where different post-depositional, pedological processes have obliterated stratigraphical detail and the deposits appear amorphous, as has been shown by studies on the origin of the early medieval dark earth deposits found in many European urban contexts (Macphail, Galinié, and Verhaeghe 2003). Geochemical analyses (see CHEMICAL MAPPING) can also be used to characterize the use of urban space, for example the location of different crafts, waste deposition, and animal housing, as well as detection of water and soil pollution, including heavy metals (Oonk, Slomp, and Huisman 2009).

The development of cities was also closely related to water resource availability. The scale and the way in which people altered or managed water resources varied greatly depending on local conditions: for instance, the construction of aqueducts in many Roman towns to overcome water shortages and, in contrast, drainage and ground reclamation in towns built up along sea shores or in river deltas (e.g., terps). Use of water for mills altered local hydrology, while different crafts (e.g., tanning) and sanitation (sewage infrastructures available or not) degraded water quality. Moreover, paved and trampled surfaces were impermeable to rainwater, which then transported pollutants and waste into streams, rivers, or other water-bodies. Eutrophication of water and heavy metal pollution of water, soil, and air (see POLLUTION AND HERITAGE CONSERVATION) had negative impacts on the cities' environments and on human health. In the crowded and poor sanitary conditions in towns, intestinal parasites and other diseases could flourish. As the eggs of common parasites (see PARASITE OVA AND CYSTS), such as whipworm (*Trichuris*) and mawworm (*Ascaris*), are usually observed in prepared pollen samples, pollen analysis from urban contexts or water bodies situated within an urban area may help in evaluation of the level of intestinal parasitic diseases in a local population.

Analysis of human remains (see BIOARCHAEOLOGY) can reveal much about past urban living conditions as well. Mortality rates, and dental and osteopathological diseases can show the effects

of poor diet, prolonged or recurring periods of famine, and environmental pollution.

Overpopulation and overuse of land, and climate change—especially drought—are understood to be among the possible causes of the collapse of some cities, concurrent with a fall of ancient states (e.g., the Maya). The role of environmental crises, as compared to political and sociocultural factors, in such declines is a matter of debate (Butzer and Endfield 2012). There is, however, no doubt that the environmental conditions were of crucial importance for both the establishment of a city and its successful functioning. Interdisciplinary research involving archaeology and different disciplines from natural sciences allows us to investigate and understand these uniquely human environments further.

Use of Biological Collections

MARK NESBITT

Royal Botanic Gardens, Kew, UK

EVA FAIRNELL

Independent Researcher, York, UK

The basic methodology for identifying biological remains from archaeological sites (“biodata”) relies on comparison of unknown material with specimens of known identity. Such known specimens exist in biological collections, held, for example, in museums and archaeological science laboratories. The term “reference collection” is often used for the latter, with the implication that the material is specifically for comparison. Common types of reference collection include seeds, pollen, phytoliths, wood and vegetative anatomy, animal bones, teeth and antlers, animal hair and skin, shells, and insects. Although still primarily gathered for morphological and anatomical comparison, biological collections have also become important as a source of DNA and for other chemical analyses, such as stable isotope investigations.

The initial sorting and identification of biodata can be carried out using printed and online manuals, but actual reference materials are essential to verify and determine more difficult identifications. Reference collections are also used to identify subsidiary parts of an organism, for example, cereal chaff or fruit stalks; and specimens with detailed provenance can give further insights, for example, teeth from known-aged animals can be used to age archaeological specimens.

National and local museums can contain many millions of biological specimens. These collections may not be designed as reference collections for use within archaeology, but they remain an essential resource for specialist work. Full acknowledgment and citation of any

specimens used as part of archaeological research should be given. Curators can also provide advice on collections care.

Forming a reference collection

Collecting and curating reference material can be time-consuming and expensive. A long-established laboratory may have thousands of specimens, many gathered directly from the field, with dedicated staff time for curation. A new laboratory or independent researcher will often start by focusing on common taxa. The concept of a “distributed collection” is increasingly being explored (e.g., Fairnell and Orton 2017) in which collections are owned and housed individually, but are databased centrally, enabling workers in one institution to locate relevant material in others.

The range of taxa to be included in a reference collection will depend on the geographical study area and time frame of interest. The biota found in the region of interest today is the obvious starting point, but over time, different species will have been present. It may therefore be necessary to look further afield to find relevant comparable, surviving biotas.

The focus of a collection will also depend on the expected preservation of archaeological material; for example, if waterlogged or desiccated plant remains are likely, a wide range of vegetative plant parts will be required, in addition to fruits and seeds. If agricultural sites are the focus, then good representation of crop varieties and farm animal breeds will be desirable. Collection of reference material can be easily integrated with ethnoarchaeological work, for example, collecting by-products of crops or animal-carcass processing.

Obtaining specimens

Reference material should be accurately identified and in good physical condition. Plant parts

such as seeds and wood are ideally vouchered by a herbarium (pressed plant) specimen bearing leaves, flowers, and so on, that can be identified by a botanist and be available for future taxonomic investigations. An insect can be preserved whole and form its own voucher. For animals such as mammals and birds, a digital image of the carcass is required before preparation.

Fieldwork for acquisition of reference material should be planned to optimize the timing, for example, to coincide with flowering season or breeding condition. Protected areas, such as nature reserves and official enclosures, can be very productive. Collecting in the vicinity of an excavation has the benefit of increased understanding of the geomorphology and vegetation, which will be valuable in interpreting biodata.

Reference material can also be acquired or donated from existing collections, for example, botanical gardens or gene banks, although the quality of such specimens should be assessed. With such material, it is advisable to have two or three different accessions for a species so they can be checked for consistency in identification. Good documentation is important; confirmation should be sought that the material offered was legally acquired and is the property of the donor.

Ethical and legal aspects

Collecting or exporting plants and animals may require permission from national or local representatives. Plants and animals listed by the Convention on International Trade in Endangered Species (CITES) will usually require both an export and import permit. When collecting is planned, it is advisable to get advice from local museums and field biologists. Collectors should also be aware of ethical aspects of collecting, for example, relating to rare plants and animals or recording of indigenous knowledge.

Preparation and storage

Plants and fungi

Plants are usually vouchered by a herbarium specimen. Macroremains such as seeds, fruits, and vegetative parts are collected into paper or

cloth bags so that they can dry without going moldy. Fruit stones embedded in fleshy fruits should be extracted before the fruit dries. Once plant materials are dry, they should be frozen at minimum -20°C for one week to kill any insect infestation. Seeds are usually kept in glass tubes or archival (e.g., polystyrene) plastic boxes in shallow drawers to allow easy browsing. Woods may be sectioned for anatomical slides, or charred for examination under an epi-illuminating microscope. Waterlogged archaeological material can be stored for reference use, either freeze-dried (risking some loss in definition) or wet in 70 percent ethanol or industrial methylated spirits (IMS), or sectioned on microscope slides using suitable mountants.

Microremains are usually also held on microscope slides, using permanent or semipermanent mountants. Starch granules (see STARCH GRANULE ANALYSIS) can be extracted from dry plant material by grinding. Pollen can be extracted from fresh or dry flowers using a brush. Phytoliths (see PHYTOLITH ANALYSIS) are extracted by ashing plant material in a muffle furnace, or treating with acid in a suitably equipped laboratory.

Plant DNA is usually extracted from leaves or seeds. It is routinely extracted from herbarium specimens up to 200 years old. However, if DNA extraction is desired from new collections, fresh leaves should be collected into paper bags, then packed in sealed plastic bags with silica gel to maintain a dry environment. If plant collections are treated with alcohol this will destroy any DNA within (Doyle and Dickson 1987).

Vertebrates

Animals should be identified to species, sex, and age, before the carcass is prepared for its skeletal and/or other relevant parts. Fresh carcasses of known animals are best, because they are easier to identify and handle.

The four main methods of bone preparation are burial, cold-water maceration, hot-water maceration, and dermestid beetles. The choice of which method to use often involves a compromise between time and smell. The quicker processes, hot-water maceration and beetles, can be the smelliest. Enzymes, such as Neutrase® and trypsin, can be used to help break down

the protein (flesh); biological washing detergents (which contain enzymes and mild bleaches) can be used to help break down protein and fat; fat can also be removed with the use of solvents, for example, acetone. Whichever method and chemicals are used, a risk analysis must be carried out beforehand to make sure the preparation is carried out safely. Fresh carcasses may be a source of zoonotic disease, such as avian flu; dermestid beetles need to be housed and cared for appropriately; and all chemicals must be used safely, following, for example, the United Kingdom's Control of Substances Hazardous to Health (COSHH) Regulations 2002 guidelines. A well-ventilated area is likely to be a prerequisite.

If any flesh or fat remains on or in the bones, the collection will be susceptible to insect and mold damage and will degrade. Fluctuations in temperature and humidity can also damage bone. Ideally, clean, dry bones should be stored in a controlled environment, with some ventilation. If stored in plastic bags, the bags should be perforated. Depending on the preparation method used, the bones may become unsuitable for future DNA analysis.

Invertebrates

Accurate identification of, for example, mollusc and insect species from the fresh specimen using relevant identification keys is vital before they are processed. A risk analysis of all processes and chemicals used should be carried out. Insect and mollusc collections can comprise many small specimens, which need to be stored in suitable boxes and trays so that they are easily accessible but protected from rough handling and light. The storage environment should be controlled to provide some ventilation and avoid fluctuations in temperature and humidity.

Insects can be pinned or mounted on microscope slides, depending on their size. Insects, and many other biological reference materials, can also be preserved in fluid, but such specimens are not as easy to use as comparanda because they cannot be readily handled. Some chemicals used to relax insects for pinning or mounting them on slides may destroy DNA. Insect collections are prone to insect attack, while mollusc collections

can be affected by acidic fumes released from organic packing material. Molluscs can be stored dry in sealed plastic bags.

Organization and cataloging

There are three ways to organize a reference collection: in an evolutionary sequence, placing related taxa close to each other; in an alphabetical system, requiring no specialist knowledge to locate taxa; or in an index collection, arranged by element and size. The choice of sequence is not always simple and advice should be sought from other laboratories or taxonomists. It is important that the correct biological nomenclature is used; this may be based on a national checklist or on an online resource such as the GBIF Backbone Taxonomy (GBIF Secretariat 2016).

A catalog of the collection, usually in the form of a database, should indicate where to find a specimen and comprehensive details of the specimen's provenance, including, for example, source location/habitat, age, life history, and cause of death. The set of fields will usually be similar to that in the Access to Biological Collections Data (ABCD) schema (TDWG Task Group 2007). The data should be atomized, for example, scientific names broken down into genus, species, and author fields, locality and country recorded separately. It is better to have a smaller number of fields that are consistently filled, than many fields that are mostly empty. Once provenance data have been added to a database, the original documentation (including permits) should be stored safely.

When specimens are integrated into a collection, they need to be given a unique accession number. In skeletal collections, that number can be written on each element; for pinned insects, the number is written on a card label; the number can also be written on the bag or container housing the specimen. If previously held elsewhere, the original collector and collection accession number should be retained, and it is good practice to cite both in reports.

Vegetation Modeling Using Pollen Data

MICHELLE FARRELL
Coventry University, UK

M. JANE BUNTING
University of Hull, UK

Palynology (see PALYNOLOGY) is one of the most commonly used methods of reconstructing the environmental context (see ENVIRONMENT AND LANDSCAPE and PALEOENVIRONMENTAL RECONSTRUCTION) of archaeological sites. Traditional interpretations of pollen records collected within archaeological landscapes have taken a broadly narrative approach, with pollen diagrams being interpreted in the form of descriptions of successive patterns of land-cover at different points in time, drawing on knowledge of plant ecology (both of individual species and of habitats such as woodland) and of land-cover types created by different human activities, with little attempt made to assess the uncertainty of the reconstruction or to use a formal hypothesis testing (see HYPOTHESIS TESTING) approach. These descriptive reconstructions provide background for archaeological interpretation (see INTERPRETATION), but are too general to be fully integrated into most reconstructions or analyses. To address this gap, pollen data need to be translated into quantitative estimates of past vegetation abundance or change and/or maps of past land-cover.

This has been an important goal for the palynological community since its earliest days. Several different approaches to this translation process have been developed, which can be grouped into two categories: those based on the characteristics of the whole pollen assemblage, and those using an algebraic model of the relationship between individual pollen types and the plants that produced the pollen. Examples of whole-assemblage techniques include the modern analog technique (MAT: Overpeck, Webb, and Prentice 1985), biomization (Prentice et al.

1996), and pseudobiomization (Fyfe, Roberts, and Woodbridge 2010). The MAT compares modern pollen assemblages with those from subfossil samples, on the assumption that modern vegetation communities which produce pollen assemblages that are statistically similar to the subfossil assemblages are good analogs for the past environment that produced them. However, the MAT can only reconstruct landscapes that have extant analogs, and many past landscapes have no modern analog—for example, the steppe and tundra vegetation in lowland Europe during the Late Glacial, or landscapes with large populations of wild mega-herbivores like aurochs. In the biomization approach, pollen taxa are assigned to one or more plant functional types (PFTs), which are broad classes defined by characteristics such as plant life form, leaf type, phenology, and climatic adaptations, and then the spectrum of PFTs present is used to assign samples (and therefore the environments in which they formed) to large-scale biomes. However, many pollen taxa can be assigned to more than one PFT, since one pollen taxon is typically made up of pollen from several different plant species with differing ecological requirements, and the reconstructions produced apply spatially at a subcontinental or continental scale, too coarse for most archaeological research questions. Pseudobiomization addresses the second problem by assigning pollen taxa to land-cover classes (LCCs) rather than PFTs, allowing inclusion of anthropogenically modified vegetation types such as pastoral or arable land, and producing reconstructions at a regional or landscape scale. However, pollen taxa cannot be assigned unambiguously to LCCs, and the first problem remains.

The second approach uses algebraic models of the relationship between plant abundance in the landscape and the pollen assemblage. Interpretation of pollen assemblages is complicated not just by taxonomic imprecision, but also because different plant species produce different amounts of pollen and exploit different pollen dispersal mechanisms, and because different sizes and types of sampling site (e.g., small lakes (see LAKE DEPOSITS); large mires (see PEAT DEPOSITS))

record the landscape with different levels of spatial sensitivity. Taxon-specific models allow these differences to be explicitly acknowledged and allowed for in the results. Most such models are linear (see *LINEAR MODELS*), although recent advances in computing power and spatial analysis are opening up a wider range of options. These models have multiple underpinning assumptions, and need to be calibrated for each pollen taxon of interest; so far, calibration datasets mostly exist for temperate ecosystems (see *TEMPERATE ENVIRONMENTS*).

The most widely used linear model (see *LINEAR MODELS*) is termed the Prentice-Sugita model (Prentice 1985), and it underlies two different process-based modeling approaches to quantitative vegetation reconstruction that are currently being actively applied: the landscape reconstruction algorithm (LRA: Sugita 2007a,b) and the multiple scenario approach (MSA: Bunting and Middleton 2009). The LRA uses an algebraic approach to reconstruction. First, pollen records from large lakes (>500 ha) are used to reconstruct the regional vegetation (within c. 100 km radius of the lake). These values are then used to calculate the pollen contribution from the regional vegetation (the “background” pollen rain) to the pollen assemblage forming in a smaller sedimentary basin (typically <10 ha), and separate that from the pollen component from the local vegetation within c. 100–3000 m of the basin, which can then be reconstructed. A significant advantage of the LRA is that a formal estimate of the spatial scale of the reconstruction is included in the output of the model, but the reconstructed vegetation abundance is expressed in terms of distance-weighted plant abundance rather than actual land-cover, and no information on the spatial arrangement of the different vegetation communities is obtained. This approach has been successfully validated against present-day datasets where both pollen and vegetation data can be measured directly, and actual vegetation can be compared with reconstructions, and applications have so far tended to focus on large-scale vegetation reconstructions addressing questions of landscape openness and changing land-cover across subcontinental scale areas.

The MSA uses an iterative approach to reconstruction. A geographical information system (GIS) is used to combine knowledge of past

environmental constraints such as topography and geology with simple ecological principles to generate possible land-cover maps for a specific area around one or more pollen sample locations. Many thousands of hypothetical land-cover maps can be generated by varying the range of values for the distribution of each community (for example, placing treelines at different altitudes, or varying sea-level for coastal communities) and randomly placing patches of vegetation communities into suitable locations in different proportions. The Prentice-Sugita model is used to simulate the pollen assemblage at each of the sampling locations for each possible land-cover map, and these pollen assemblages are then compared with the actual assemblages recorded using the same statistical approach as the MAT. Where actual and simulated assemblages are statistically very similar, the possible land-cover map is considered to be a “modeled analog” of the past landscape. One strength of this approach is that it can identify equifinal solutions, situations where ecologically distinct land-cover arrangements can produce statistically indistinguishable pollen assemblages, which can then form a basis for future hypothesis testing (see *HYPOTHESIS TESTING*).

An intermediate approach takes a limited number of simplified possible past land-cover maps and uses the Prentice-Sugita model to simulate pollen assemblages for comparison with subfossil records. This multiple hypothesis testing (see *HYPOTHESIS TESTING*) framework allows better understanding of the responsiveness of the pollen signal to changes in land-cover arrangement (e.g., Tipping et al. 2009), and can be an effective means of exploring whether pollen analytical methods can actually be used to test archaeologically derived hypotheses of past landscape organization, or to inform or underpin reconstructions used for education and outreach (see *HERITAGE INTERPRETATION*), such as artists’ reconstructions and virtual reality modeling (see *VIRTUAL REALITY MODELING*). The technology used to produce digital reconstructions is often so sophisticated that they may be uncritically accepted as being scientifically accurate, and pollen-based hypothesis testing may offer a useful method for improving the quality of the input information.

Both the LRA and the MSA are best used with pollen records from multiple sites, which require robust chronologies to ensure that age-equivalent pollen assemblages are compared, and are limited by the assumptions and model-calibration needs of the Prentice-Sugita model. A key issue concerns the measure of the amount of pollen produced by different plants, or relative pollen productivity (RPP). To date, most published RPP estimates are from northern Europe and North America, although some values are available for sites in Africa and Asia, and research is currently underway to extend this coverage. Both approaches effectively assume that RPP is a constant within a geographical region, both in time and space, and therefore that changes in pollen proportions through a sediment core are entirely produced by changes in the abundance or position of vegetation around the sampled sedimentary basin. However, a review of published RPP estimates across northern Europe showed that estimates were highly variable (Broström et al. 2008); this may reflect real differences in RPP related to climate or land management (e.g., in a pasture, grasses flower less profusely than in a hay meadow, and therefore the amount of pollen produced will vary markedly even though both systems are dominated by grasses), or be an artifact of differing methodologies or small datasets, since vegetation survey for such studies as currently practiced is highly labor-intensive.

Pollen-based reconstructions of past land-cover can be used as the basis for future research, especially within a hypothesis testing (see HYPOTHESIS TESTING) framework. Drawing on multidisciplinary datasets from both on-site and off-site contexts using a wide range of proxies for past environments such as insect remains (see ARCHAEOENTOMOLOGY), molluscs (see LAND AND FRESHWATER MOLLUSCS) and plant macrofossils (see PALEOETHNOBOTANY) can both add detail to the reconstructed landscape and enable the analyst to distinguish between alternatives that cannot be separated using pollen data alone. Landscape archaeological research can also be used to construct or test hypotheses of land-cover organization, and to constrain pollen-based reconstructions.

As computing power and speed increases, alternative approaches to studying past vegetation cover become possible. Dynamic vegetation

models such as LPJ-GUESS or FORMOD incorporate a range of plant physiological processes to model how vegetation communities may change in response to changes in parameters such as climate or atmospheric carbon dioxide levels, and these models have been applied to attempt reconstructions of possible past vegetation over archaeologically relevant timescales. Testing the outputs of such models against pollen data is rarely done, and the modeling approaches discussed here may offer new opportunities to bring together the sophisticated modeling of plant ecological research with environmental archaeology (see ENVIRONMENTAL ARCHAEOLOGY), to the benefit of both.

Water Pollution

KAREN A. HUDSON-EDWARDS

University of Exeter, Penryn, UK

Water pollution is arguably one of the most significant issues that has faced humanity over the ages because it adversely affects the health of billions of people globally, leading to diseases such as cholera, diarrhea, and cancer. Water systems, for example, have been polluted with human waste for millennia, causing cholera outbreaks and pandemics that have killed millions of people (Morris 2011). The mining of metal-bearing ores has contaminated water systems and caused extensive human lead and mercury poisoning (Pyatt et al. 2005; Robins 2011). Water pollution has also affected the health of ecosystems, causing changes in diversity, population density, disease, and death (Neto et al. 2016).

Water can be polluted by metals and metalloids such as arsenic, cadmium, lead, and mercury, by organic compounds such as manure or sewage, by radionuclides (radioactive isotopes; see ISOTOPES) such as cesium-137 and uranium-138, by nutrients such as phosphate and nitrate, and by acids or bases. These elements and compounds occur naturally in low to high concentrations in waters due to the weathering of rocks and soils and the decomposition of organic materials. They can be added to rivers, lakes, glaciers, the atmosphere, groundwaters, and oceans by natural events such as volcanic eruptions, floods, and landslides. Alternatively, anthropogenic activities such as mining, agriculture, manufacturing, and urbanization can pollute waters through runoff, accidental spills, seepages from cesspools, or from mine wastes. Some of these anthropogenic activities, especially those related to inadequate water purification, can also result in the pollution of water by pathogens such as *Escherichia coli* and cholera, or by heat, forming thermal pollution.

Pollutants enter water systems from “point sources” or “diffuse sources.” Point sources are single discharge positions, and examples include mine adits, sewage outlets, and latrines. Diffuse sources are those with multiple discharge positions. These include leaching of mine waste piles, atmospheric fallout, flooding, and agricultural runoff. In Ireland, for example, carbon and nitrogen isotope geochemistry of lake sediments, along with pollen and charcoal analysis, has been used to show that Neolithic and Bronze Age farming caused changes in chironomid subfossil community compositions (Taylor et al. 2017). Another example of diffuse pollution is that of mining-contaminated rivers. The channel and floodplain sediment of these systems has been enriched in metals such as lead, zinc, and cadmium through the ejection, in some cases over hundreds to thousands of years, of mine waste material into river systems (see RIVER SYSTEMS). These sediments act as a diffuse source of metals to waters through physical and biogeochemical weathering, and this is often a more significant pollutant source than the weathering of mine waste tips that line the rivers (Macklin et al. 2006).

Because ancient waters are rarely preserved, the unraveling of the historical effects of water pollution involves the use of “environmental proxies,” preserved physical, geochemical, and biological materials within the geologic record that can be analyzed and dated to reconstruct past conditions (USGS 2017). Current research on historical water pollution focuses on determining its effects on past populations and on using and developing such environmental proxies for studying water quality. In many cases, sediment cores (see CORING) are used for these studies, because they provide a temporal record extending back tens to hundreds or thousands of years and contain proxies such as foraminifera, diatoms, and pollen, while the sequence of deposits can be analyzed for their geochemical signatures that in turn give direct information about water pollutants. For example, Neto et al. (2016) collected

sedimentological, foraminifera, pollen, and geochemical data for the last 5,000 years from cored sediments from Guanabara Bay, Brazil, and defined three stages of environmental history in the area. The most recent stage, occurring in the last few hundred years, was characterized by metal pollution (lead, nickel, copper, chromium, zinc, manganese) that leads to vegetation change and environmental deterioration. Nitrogen and carbon isotopic and trace metal geochemical data from sediment cores were used to demonstrate that Xing Yun Lake in Yunnan Province, China, was polluted as far back as 500 CE (Hilman et al. 2014). The taxonomy and morphological changes in diatoms (see DIATOMS) in a sediment core from Lac Dufault, Abitibi, Canada, were shown to shift and progressively deform, respectively, due to water metal pollution arising from mining (Cattaneo et al. 2004). Parasites (see PARASITE OVA AND CYSTS) found in latrine and cesspool sediments from the Middle East have confirmed cases of dysentery in Jerusalem in the Middle Ages (Mitchell, Stern, and Tepper 2008).

Future research on past water pollution will continue to determine its spatial extent and effects on humans and ecosystems. To achieve this, the physical, geochemical, and biological proxies developed to date will continue to be used, and these will be improved and augmented by new techniques. For example, ancient DNA has recently been profiled from a nineteenth-century cholera intestinal specimen and a medieval Black Death plague victim's tooth using a microarray detection technique. This technique has been proposed to be a rapid and inexpensive screening tool for similar archaeological samples (Devault et al. 2014). The exposure of people living in the Atacama Desert in Chile from 500–1450 CE to naturally occurring arsenic has been assessed using synchrotron radiation (Kakoulli et al. 2014). High concentrations of inorganic arsenic have been found in hair samples, suggesting chronic uptake of the element from polluted waters. Because synchrotron radiation has much higher intensity than that generated conventionally, it can be used for very small samples with low elemental concentrations, and therefore has great applicability for archaeological studies of water pollution.

Wheat

BURHAN ULAŞ

Alata Horticultural Research Institute, Turkey

HALİL ÇAKAN and HAKAN ÖZKAN

University of Çukurova, Turkey

Cereals account for more than 50 percent of worldwide crop production and are important renewable resources for food, feed, and industrial materials. Wheat is the primary cereal of temperate regions and the staple food for about 40 percent of the world's population. It is commonly recognized as a grass, as a kernel of wheat is the caryopsis or fruit of a plant of the genus *Triticum* from the grass family (Poaceae).

Wheat provided the agronomic basis for development of the earliest groups in Mesopotamia, and has been found at archaeological sites in the region dating back to 12,000 BP. The spread of wheat from its site of origin across the world has been elegantly described by several researchers and is only summarized here. The main route into Europe was via Anatolia to Greece (8000 BP) and then both northwards through the Balkans to the Danube (7000 BP) and across to Italy, France, and Spain (7000 BP), finally reaching the United Kingdom and Scandinavia by about 6000 BP. Similarly, wheat spread via Iran into central Asia, reaching China by about 3000 BP, and to Africa, initially via Egypt. It was introduced by the Spaniards to Mexico in 1529 and to Australia in 1788 (Abbo et al. 2013). Nowadays, wheat is grown on every arable continent, and it is the most important food for people living in temperate regions of the world.

The most important wheats are: bread (*Triticum aestivum*), used to make bread; durum (*T. durum*), used to make pasta, couscous, and bulgur; and club (*T. compactum*), used to make softer cakes, crackers, cookies, and pastries. Additionally, some wheat is used by industry for the production of starch, malt, and other products. Small amounts of other wheat species

(einkorn, emmer, spelt) are still grown in some regions including Spain, Turkey, the Balkans, and the Indian subcontinent, while spelt continues to be grown in Europe, particularly in Alpine areas (Kilian et al. 2009).

Nearly a century ago, it was determined that the cultivated wheat species of the genus *Triticum* have chromosome numbers of $2n = 14$, 28, and 42. This indicated that the basic Triticeae genome is organized into seven chromosomes ($x = 7$) and the various *Triticum* species consist of diploids ($2n = 2x = 14$), tetraploids ($2n = 4x = 28$), and hexaploids ($2n = 6x = 42$) (Faris 2013). The first wheat to be cultivated successfully was einkorn (*T. monococcum*), a diploid species ($2n = 2x = 14$, $A^m A^m$). The site of domesticated einkorn wheat, according to genetics and archaeological studies, is found in the Karacadağ mountain region of Diyarbakır, Turkey. Although einkorn was important for Neolithic agriculture, today it is a relic crop and is rarely grown (Heun et al. 1997). A further important step in the evolution of wheats was the domestication of emmer, which is a tetraploid wheat ($2n = 28$), from its wild progenitor *T. dicoccoides*. Wild emmer, an AABB wheat, with its A genome derived from *T. urartu* and its B genome probably derived from the S genome present in the *Sitopsis* section of *Aegilops*, with *Ae. speltoides* being the closest extant species, has brittle ears that shatter at maturity into spikelets that bear relatively large grains. Unlike their wild progenitor, all domesticated tetraploid wheats have a nonbrittle rachis, which is more amenable to harvest as the ears do not fall apart. Domesticated emmer wheat, *T. dicoccum*, has hulled grain and the AABB genome that is common to other domesticated tetraploid wheats (Faris 2013). Emmer was first cultivated in the southern Levant (Netiv Higdud, Tell Aswad, other PPNA sites), while einkorn is found in northern Pre-Pottery Neolithic A (PPNA) sites (Abu Hureyra, Mureybet, Jerf el Ahmar, Göbekli Tepe, other southern PPNA) (Özkan et al. 2010).

The wheat species with tetraploid genomes were subsequently involved in accidental

crosses with a wild diploid species (*Aegilops tauschii*), giving rise to hexaploid wheats. Domesticated hexaploid wheats have no wild hexaploid progenitor in nature; it is, therefore, a farming-associated natural hybrid that has since become the world's leading crop. The appearance of the free-threshing phenotype can be illustrated with the comparative genetics of two hexaploid wheat varieties, *T. spelta* (spelt wheat) and *T. aestivum* (bread wheat, a free-threshing form). Both *T. spelta* and *T. aestivum* have an AABBDD hexaploid genome (Kilian et al. 2009).

The main difference between the wild forms of wheat and domesticated wheat is that domesticated forms have a nonshattering rachis. When wild wheat is ripe, the rachis—the stem that keeps the wheat ear together—shatters so that the seeds can disperse themselves. This is clearly an important trait for ensuring seed dispersal in natural populations, but meant that the ears broke up when harvested by people using cutting tools or plucking by hand. Plants with a non-shattering rachis, determined by mutations at the *Br1* (brittle rachis) locus, were preferentially selected as a result of these harvesting techniques, leading to the fixing of this trait in domesticated wheats. The second important trait found in domesticated wheats is the change from hulled forms, in which the glumes adhere tightly to the grain, to free-threshing (naked) forms, where the grain is held loosely within its chaff. The free-threshing forms are caused by a dominant mutant at the *Q* locus, which modifies the effects of recessive mutations at the *Tg* (tenacious glume) locus. The early-domesticated forms of einkorn, emmer, and spelt are all hulled, whereas modern forms of tetraploid and hexaploid wheats are free-threshing (Faris 2013).

Together with diploid and tetraploid species, free-threshing hexaploid wheat has been identified in the settlements of Abu Hureyra 2A, Cafer Höyük, Çayönü, Tell Aswad II, Aşıklıhöyük, Ghorraife, and Tell Halula within the so-called Fertile Crescent, which is located in the Middle East and encompasses a region extending from Jordan, Israel, Lebanon, and Syria through southeast Turkey and along the Tigris and Euphrates rivers through Iraq and western Iran. *Triticum monococcum* and *T. dicoccum* have also been identified in all the settlements in the Near East,

but hexaploid species such as *T. aestivum* Host and *T. spelta* have not.

Compared to the diploid and tetraploid species, the origin and spread of the hexaploid species is poorly understood. The genetic data indicate that hulled hexaploid wheat species are more “primitive” than free-threshing hexaploid wheat species. However, contrary to the genetic data, the oldest findings in archaeological record are of free-threshing hexaploid species.

The distribution of *Ae. tauschii*, the source of the D genome in the principal hexaploid wheats, covers a very large area, from northeastern Anatolia to Armenia, Azerbaijan, the coast of the Caspian Sea, Pakistan, Afghanistan, and the northeastern part of Kyrgyzstan. The range of *Ae. tauschii* hints at its adaptation to various climatic and environmental conditions: from the desert-like environment of the mountain foothills of Afghanistan to the mild climate of the Caspian Sea coast. Furthermore, the identification of this species in northeastern Anatolia, where continental climate conditions and steppe plant cover prevail, but not around the Karacadağ region, where the wild progenitors of *T. dicoccum* and *T. monococcum* have been identified, seems like a remarkable contradiction—especially as some researchers attribute the adaptation of *T. spelta* to mild humid or harsh continental climate conditions as due to the incorporation of the *Ae. tauschii* genome.

However, the identification of *Ae. tauschii* around Şanlıurfa, where Çayönü, Nevalı Çori, and Göbekli Tepe settlements were located, suggests that the natural geographical range of *Ae. tauschii* extended into this region in the past and that *T. spelta* may have first been grown in settlements in the foothills of Karacadağ. Indeed, *T. aestivum* ssp. *compactum* has been identified in Can Hasan III, *T. aestivum/durum* in Çayönü, and rachises of bread wheat in Caferhöyük III and IV levels (Zohary, Hopf, and Weiss 2000).

The question of the geographic origin of wheat domestication has been the subject of much research. Recently, based on archaeological, archaeobotanical, and genetic evidence, a well-defined “core area” hypothesis was suggested. The core area hypothesis maintains that the Near Eastern Neolithic crop package, including both cereals and legumes, was domesticated within a relatively restricted area in southeastern

Turkey once or a very limited number of times; that is, there was monophyletic domestication (Abbo, Lev-Yadun, and Gopher 2012; Abbo et al. 2013). An alternative hypothesis favors a geographically diffused Near Eastern wheat domestication pattern, comprising a series of separate events in which wheats were domesticated through a sequence of genetically and culturally independent occurrences. The debate concerning “core area” versus diffused domestication is still part of the discussion on Near Eastern plant domestication (Fuller, Willcox, and Allaby 2011). Therefore, there is still much work needed to understand plant domestication models, particularly for wheat domestication.

The *Triticum new glume wheat* type

The recent study of vegetal macroscopic plant remains from Anatolia once again shows the strategic role of the region in the origin of wheat domestication. Archaeobotanical investigations have shown that the *Triticum new glume wheat* type, a type of wheat that has only been identified archaeologically as macroscopic plant remains (Jones, Valamoti, and Charles 2000), has been used since the ninth millennium BCE. The earliest records so far come from the following Anatolian sites: Pre-Pottery Neolithic B (PPNB) Caferhöyük, Pottery Neolithic (PN) Çatalhöyük, PN Yumuktepe, and PN Yenikapı.

The identification of *Triticum new glume wheat* type is rather complex, because the caryopsis does not always allow precise identification. For this reason, researchers mostly use glume bases for taxonomical resolution. Identification is possible through the analysis of the fork's morphology, especially through the wide and deep scar left by the disarticulation of rachis. This taxon, according to some authors, belongs to the tetraploid group. Among the possible tetraploid cereals that the *Triticum new glume wheat* type might have sprung from are wild species like *T. diccoides* and *T. timopheevi* ssp. *araraticum*.

Although the analyses carried out so far have enabled the proposition of several theories on the taxonomical origin of *Triticum new glume wheat* type, they have not been able to entirely clarify the other problems regarding this species

(origin, diffusion, etc.) Therefore, more reliable archaeobotanical data and analytical tools are required in order to propose more precise theses regarding the taxonomical origin of this problematic species.

Current knowledge of wheat domestication is largely derived from morphological analysis of archaeobotanical remains and population genetic analysis of present-day samples. However, with the advent of ancient DNA analysis, in particular next generation sequencing (NGS), it is possible to carry out analysis of charred cereal grain, allowing the stages of wheat domestication to be presented in dimensions of time and space, including the genetic make-up of *Triticum new glume wheat* type.

Zooarchaeology

TERRY O'CONNOR

University of York, UK

Zooarchaeology is the discipline of archaeological science that seeks to understand past interactions between people and other animals through investigation of the archaeological record. The term *archaeozoology* is also used, particularly in Europe: The two terms are effectively synonymous. The principal study materials for zooarchaeology are the physical remains of animals themselves; hence the research literature mostly presents studies of bones and marine shells (see MARINE MOLLUSCS). However, other forms of evidence are pertinent, such as tracks and trails, enclosures and droveways, skin, hair, and feces (see COPROLITES), and bone and shell artifacts. The use of insect (see ARCHAEOENTOMOLOGY) and nonmarine mollusc (see LAND AND FRESHWATER MOLLUSCS) remains as paleoenvironmental evidence could also be subsumed under zooarchaeology, but are generally regarded as separate disciplines. Zooarchaeology uses essentially the same working methods as paleontology—systematic identification of specimens, analysis of depositional context, and inference of individual and population health and behavior—with the important difference that human interaction with the animals is at the center of the study, hence the focus on vertebrate and large invertebrate animals that have been hunted, farmed, or foraged. When investigating animal remains from early hominin sites, the differentiation of zooarchaeology and paleontology is more problematic, especially when dealing with animal species that are now extinct.

The earliest instances of people wondering about ancient animal bones and shells are lost in prehistory, though examples of the apparent curation of old bones are occasionally recognized in the archaeological record. The systematic study of excavated animal remains for what they show of past human entanglements with animals is

at least as old as archaeology itself. From the mid-nineteenth century onwards, antiquarianism developed into archaeology under the twin influences of evolutionism and positivism (see POSITIVISM) and the development of zooarchaeology was part of that process. A key project was Ludwig Rütimeyer's pioneering study of animal bones from the "lake-village" sites of Switzerland (Rütimeyer 1861) in which he sought to understand the bones both as evidence of the economy of the settlement sites and of the natural history of their region. In particular, Rütimeyer tried to differentiate bones of wild and domesticated forms of the same species, such as pigs and wild boars, anticipating a major theme of later zooarchaeological research (see PIGS). Meanwhile, work had begun in Denmark to systematically investigate bones and shells from the many large prehistoric middens (Køkkenmøddinger) in that country (Andersen 2000). Other shell and bone middens attracted attention. Some of the earliest zooarchaeological work undertaken in North America was carried out by William Dall (1877) during his pioneering investigation of archaeology and ethnology in the Aleutian Islands and Alaska. On the Atlantic coast, sporadic work on shell middens in Maine began around the same time. Writing in 1912, Thomas Joyce gave the first published account of the huge *sambaqui* middens of coastal Brazil, comparing them with the Danish middens. Most of these early midden investigations used bones and shells as evidence of foraging and diet. In Paleolithic sites in Europe, based more on Pleistocene deposits in caves, large mammals were used as biostratigraphic markers in floating chronologies (see QUATERNARY LARGE-MAMMAL ZONES). Differentiation of a "Mammoth Age" from a "Reindeer Age" was crude, but it at least recognized the value of excavated bones as indicators of environmentally driven regional changes of biota and allowed some regional stratigraphic frameworks to be proposed.

Zooarchaeology in Europe and North America thus has its roots in the 1860s and 1870s. Despite that early start, and with a few notable exceptions, adoption of the systematic study

of excavated bones and shells was slow and piecemeal until well into the twentieth century. The procedures that underpin zooarchaeology today were largely developed in the second half of the twentieth century as zooarchaeology moved away from paleontology, in particular through the use of ethnographic analogy (see ETHNOARCHAEOLOGY) to propose that social and economic aspects of food sharing and economic behavior could be inferred from excavated bone assemblages. Theodore White's observations of bone deposition by Native Americans continue to be influential, as does the work of Lewis Binford in Arctic North America and of Bob Brain in southern Africa (Lyman 1994). One criticism that is directed at this phase in zooarchaeology's development is that it assumed that past peoples behaved rationally and optimally in their selection of prey and utilization of carcasses, despite some ethnographic evidence that this is not always the case. The emergence of social zooarchaeology in the 2000s can be seen as a reaction to those normative assumptions (Russell 2012). The 1960–1970s saw zooarchaeology extend into Central and South America, and especially in southwest Asia, followed in subsequent decades by important research in East and Southeast Asia and Australasia. At the time of writing, sub-Saharan Africa stands out for its undeveloped potential for zooarchaeology, despite excellent work by a few individuals.

Although the research agenda of zooarchaeology differs from project to project, certain techniques of data acquisition have dominated the development of the discipline. Taphonomy (see TAPHONOMY), the analysis of assemblage deposition and diagenesis, has been the elephant in zooarchaeology's closet ever since Rüttimeyer's pioneering work. Paleontologists have understood the importance of taphonomy for many decades. Weigelt studied the postmortem degradation and weathering of animal carcasses in the 1920s, and Efremov introduced the term "taphonomy" to paleontology in 1940. As early as 1938, Pei Wen-Chung undertook a pioneering analysis of breakage patterns and cut and tooth marks on bones from Paleolithic sites in China, seeking to differentiate traces of human activity from the action of scavengers and erosion. The Paleolithic continued to be the main focus for taphonomic studies in zooarchaeology, reflecting

the considerable overlap between paleontology and Pleistocene zooarchaeology (Shipman 1981). Although textbooks conventionally discuss taphonomy, often presenting "flow diagrams" of the various filters that stand between the researcher and the ancient animals, analysis of the depositional history of zooarchaeological assemblages has yet to become a standard element of every project. Even where assemblage taphonomy is discussed, the emphasis tends to be on the loss of information rather than on using the taphonomic evidence in order to gain information about deposit formation. The work of Lee Lyman (1994) has done much to bring the potential of taphonomic analysis to zooarchaeology's attention.

The techniques of taphonomic analysis are essentially those of good observation: differentiating fractures that occurred when the bone was "fresh" or already weathered, recognizing subaerial erosion and weathering, distinguishing purposeful cut marks from chance abrasions, identifying the species responsible for tooth marks and gnawing damage. The interpretation of cut marks from butchery is particularly complex. They integrate the musculoskeletal anatomy of the animal carcass, the custom of the people concerned, and the competence and habits of the individual butcher. Diagenetic change in bone is highly complex and context-specific, though changes in nano- to microscale porosity are clearly significant. Bone is a composite of a mineral phase (bioapatite) and an organic phase (collagen), each of which conveys some protection from chemical alteration to the other phase. Diagenetic questions relating to shell middens are somewhat simpler than for bone, as mollusc shells are essentially calcium carbonate in varying proportions of calcite and aragonite. Although generalizations can be made up to a point, such as that bone and shell will be more likely to survive burial in neutral to alkaline deposits than in acidic sediments, context-specific conditions may vary over very short distances. The presence of shells, for example, may raise local pH and so protect bone in the same deposit, or the shells may, by opening the texture and therefore drainage of the deposit, accelerate bone deterioration through water and air permeation. Food debris deposits that include quantities of bone, shell, and ash may be geochemically highly distinctive, with

unexpected consequences for the deterioration of different materials.

Identification is perhaps the most basic yet challenging procedure in zooarchaeology. A typical excavated bone or shell assemblage combines fragments from an unknown number of individuals of unknown species. The identification categories used in zooarchaeology do not always directly equate to Linnaean species names, and the term “taxa” is preferable. Taxa such as “sheep/goat” or “medium venerid” are used of necessity where differentiation to a more precise level is not possible or justifiable. Identification of bones proceeds by recognition of the skeletal element, based on a knowledge of the tetrapod skeleton, then attempts to attribute the specimen to as low a taxonomic level as the observable details of the specimen will allow. Obviously this depends on the experience and rigor of the researcher concerned and their access to good comparative collections of modern specimens (see *USE OF BIOLOGICAL COLLECTIONS*), so there are significant issues around validity and quality control. One particular problem is the temptation to ascribe a specimen to a particular species because it is thought to be the most likely to occur at that time and place, rather than because of specific anatomical criteria. Biometric techniques may allow differentiation of some groups of closely related taxa, or at least indicate the probability that more than one species is present. Biomolecular analytical methods that can distinguish variations of protein and DNA chemistry (see *ZOOARCHAEOLOGY AND ANCIENT DNA*) provide a means of “cross-checking” the identification of key specimens. These laboratory methods are not applicable to every fragment in a large assemblage, but have proved their worth in identifying the raw material source in bone and shell artifacts (e.g., see Demarchi et al. 2014 for shell; Welker et al. 2015 for bone).

The measurement of animal bones has had a revered place in zooarchaeology since the late nineteenth century, when Pitt-Rivers compared measurements of prehistoric sheep from southern England to those of extant “primitive” breeds. The rationale for acquiring biometric data is not always clearly stated but is generally to allow either quantified sample-to-sample comparison of a given species, testing for significant intersample differences, or analysis of

within-sample variation, often in the hope of identifying males, females, and (in domesticates) male castrates. The domestication of livestock was often accompanied by size changes, and simple biometric comparisons are often used to differentiate, for example, domestic pig from wild boar or domestic cattle from aurochs. The data are usually simple linear measures between anatomical landmarks, following a set of standards such as those published by von den Driesch (1976). Analysis generally begins with univariate bar graphs to explore size variation, and bivariate scattergrams to investigate covariation of size and proportion, for example in lengths and breadths of a skeletal element. The fragmentation of archaeological bones means that even a large assemblage will yield relatively few measurable specimens of any one element. To maximize data utility, a range of size-scaling methods have been used, in particular a log-ratio technique based on methods developed by paleontologist G. G. Simpson. These size-scaling methods convert each observed measurement to a ratio of a standard individual or sample, allowing direct comparison of measurements taken on different parts of the skeleton. Similar challenges arise with shells. Assessment of the size range may be informative regarding harvesting strategies and subsistence yield, but breakage of shells makes such assessment difficult, necessitating means of reconstructing overall size from surviving fragments.

Multivariate analyses (see *MULTIVARIATE ANALYSIS*) of size and shape are mostly applied to bones and teeth, and tend to be eigenvector-based, such as the use of principal components analysis to explore the maximum differentiation between samples of different provenance, or of discriminant function analysis to examine the distribution of “unknown” archaeological specimens against “known” groups such as closely related taxa. These techniques are increasingly replaced by more subtle analysis of shape as captured by geometric morphometric techniques (GMM) (see *GEOMETRIC MORPHOMETRICS*). Based on the analysis of “clouds” of landmark points in multidimensional space, GMM techniques allow complex analysis of shapes that are difficult to parameterize using conventional biometry, in particular teeth.

Investigation of the animal bone record has focused on the phenotype, as proxy evidence of the genotype. Analysis of ancient DNA (aDNA) recovered from bone allows a more direct approach, using both ancient and modern biomolecular evidence to assess population movements and changes. The impact of aDNA has been to make it possible to ask questions that would once have seemed unanswerable and therefore pointless, in particular questions regarding intraspecies variation and the recognition of regional demes (Brown and Brown 2011). This has allowed detailed questions to be asked about, for example, the spread of domesticates from their source populations into new regions. Although aDNA analysis initially suffered reputational damage from high cost and modern contamination, next generation sequencing (see DNA: NEXT GENERATION SEQUENCING) has reduced the cost and enhanced the sensitivity by orders of magnitude, and the challenge for zooarchaeology today is how to manage the huge volumes of data produced by aDNA laboratories. Further developments have included the identification of animal DNA in sediment sequences, allowing species to be placed in time and space in the absence of their bones, and recovery of DNA from dated parchments, giving precisely dated genomic data for (mainly) cattle and sheep. To date, there has been little success in aDNA analysis from mollusc shells, although DNA-based identification of ancient avian egg-shell has been successful.

The study of mortality profiles is central to zooarchaeology, as it reflects human decision making in hunting strategies or in the management of domestic herds and flocks. The age of vertebrate animals at death is usually estimated by combining the state of eruption and attrition of the teeth and the state of fusion (i.e., maturity) of limb elements. Dental analysis is generally regarded as being the more precise and more reliable, as post-cranial growth and maturation can be subject to environmental effects such as undernutrition and the castration of males. Influential early work on the interpretation of domestic mammal mortality proposed idealized culling models for sheep and goats on the basis that husbandry would target meat, milk, or wool production. These models have been widely applied, often in cultural contexts quite

different to those for which they were developed, and have been criticized for being improbably normative and insufficiently case-contingent. As elsewhere in zooarchaeology, the assumption of rational, economically optimizing behavior on the part of livestock keepers may be misleading, and early models were simplistic in their allowance for risk mitigation. Many prey and domestic animals breed in a predictable season, so precise knowledge of age at death can yield information about seasonal activity. If bison can be expected to have given birth in the spring, then an excavated assemblage that includes animals of around 8 months, 20 months, and 32 months of age, but none of around 12–16 months, probably represents a winter kill. Seasonal analysis is most straightforward in the case of coastal birds (see BIRDS), which may only be accessible during the nesting season, when immature bones may comprise much of the zooarchaeological record (Serjeantson 2009). Mollusc shells grow incrementally as the animal ages, so a large shell is an old individual. Some species show incremental growth structures in shell cross-sections, which can be used to estimate age at death and season of collection. These incremental analyses, termed *sclerochronology*, have been successfully applied in many parts of the world.

The analysis of *stable isotopes* of constituent elements in bone and shell is making an increasingly important contribution to zooarchaeology (see ISOTOPES). Combined with *sclerochronology* of shells, analysis of oxygen isotope ratios ($^{18}\text{O}/^{16}\text{O}$) (see MOBILITY AND OXYGEN ISOTOPES) as a proxy record of water temperature can refine evidence of seasonal harvesting as well as providing environmental evidence. Oxygen isotope analysis has also been applied to mammal tooth enamel for paleoclimate records. Isotope ratios of carbon ($^{13}\text{C}/^{12}\text{C}$) (see DIET AND CARBON ISOTOPES) and nitrogen ($^{15}\text{N}/^{14}\text{N}$) (see DIET AND NITROGEN ISOTOPES) derived from bone collagen are used to investigate diet, the carbon ratio reflecting different sources of terrestrial and marine input and the nitrogen ratio reflecting trophic level. These dietary analyses can shed valuable light on the interaction of people and other species such as dogs and chickens by showing whether the animals had a similar diet to their human contemporaries, a useful criterion in recognizing companion animals (see COMPANION ANIMALS).

The strontium ratio ($^{87}\text{Sr}/^{86}\text{Sr}$) (see MOBILITY AND STRONTIUM ISOTOPES) is proving useful in zooarchaeology, usually measured in tooth enamel. This ratio is responsive to regional geology, being highest in ancient rocks such as granites and gneisses, and lowest in recent sediments and young extrusive igneous rocks. By comparing skeletal strontium isotope ratios with the ratio characteristic of the findspot, it may be possible to demonstrate that animals or parts of them were moved over considerable distances before deposition.

Turning from the practical to the more thematic, Paleolithic zooarchaeology necessarily focuses on hunting, and differentiating assemblages that result from people hunting from those resulting from scavenging, or even food debris of predators that have hunted people (Brain 1981). By examining bone surfaces to show, for example, whether predator tooth marks consistently underlie or overlie stone-tool cut marks, the pre-depositional processing of the bones can be determined. Disproportionate representation of particular body parts may also show whether acquisition was selective, with only certain parts of a carcass brought to a home base for consumption on the grounds that elements such as the head that were heavy but with a low proportion of usable flesh would be left at the kill-site. One weakness of this line of argument is that the edible internal organs such as heart and liver leave no archaeological trace, and the perception of what is usefully edible is subject to local custom and practice. For the Middle and Upper Paleolithic, the emphasis is more on prey selection and what this might reveal about the regional environment and decision making by the group. An important theme is the distinction between the highly targeted hunting seen, for example, in the Great Plains of North America and the broad-spectrum foraging seen, for example, in tropical Southeast Asia and southwest Europe. Optimal foraging models have been applied as explanatory devices, to show when narrow- or broad-spectrum hunting might have been the more efficient, but these approaches are not without their critics.

The exploitation of marine and freshwater fish in different societies has been a specialized area of study within zooarchaeology, not least because of

the particular challenges presented by the reliable identification of fish bones and scales (see FISH). The identification of intertidal, inshore, and offshore (see DEEP-SEA FISHERIES) fish species, especially when combined with studies of marine molluscs, can yield very detailed evidence of resource exploitation. Zooarchaeological data relating to species' past distributions and size range also make a significant contribution to contemporary debates on overfishing and the management of marine resources.

Unsurprisingly, animal domestication and its origins (see DOMESTICATION) have been major topics in zooarchaeology (Zeder, Emshwiller, and Smith 2006). A range of criteria has been recommended for the differentiation of wild and domestic forms of taxa such as caprines (see SHEEP AND GOATS) and camelids (see LLAMAS AND ALPACAS). These include changes in bone size and morphology, mortality profile, and distribution relative to a presumed wild range and habitat. Any of these would have to be accompanied by other archaeological evidence consistent with a pastoral or agrarian lifestyle, and none of them is reliably diagnostic. Size changes may indicate the emergence of a "domesticated" deme, but could also be an ecophenotypic response to some other environmental pressure. Changes in distribution might reflect the active translocation of domestic stock by people, but could be the consequence of community dynamics such as a reduction of predator pressure or regional changes in vegetation and soils. Much of the discussion of domestication in zooarchaeology has focused on caprine domestication in the wider Middle East, with a tendency to argue from that specific case to generalizing theories of animal domestication. As zooarchaeology has become a mature discipline in more parts of the world, the applicability of Middle Eastern or European models of animal domestication to other regions has increasingly been questioned, as has the underlying paradigm that domestication was a one-way process of people acting upon passive animal populations, and even the binary distinction between human and animal (see HUMANITY AND ANIMALITY). These trends in interpretation have revived interest in animal paleopathology (see PALEOPATHOLOGY). Signs of disease and injury in the bones of domestic livestock will reflect the management of those animals and

perhaps how they were regarded and valued. This approach has moved animal paleopathology away from simply “stamp collecting” interesting specimens of disease or injury.

In complex societies, especially in urban settlements (see URBAN ENVIRONMENTS), the population consuming animal resources is spatially and behaviorally removed from the production of those animals, adding a supply chain and further levels of decision making to the zooarchaeological interpretation. Contextual variation in assemblages from a large settlement may reflect socioeconomic stratification (“status”) or the location of carcass-based crafts such as tanners and horn-workers. Urban zooarchaeology presents distinctive challenges of spatial complexity and taphonomy, making a fine-grained contextual approach essential. However, the potential of an integrated analysis of bones, shells, and artifacts for detecting the socioeconomic characteristics of individual properties or neighborhoods is considerable.

Although zooarchaeology is largely concerned with the subsistence use of animals, animals living and dead have been used in ceremonial and symbolic ways since early prehistory. The inclusion of animal bodies and parts in human burials is widespread and often difficult to understand. For example, a Natufian burial from present-day Israel included remains of 50 tortoises and parts of a wild boar, a cow, a leopard, an eagle, and an additional human foot (Grosman, Munro, and Belfer-Cohen 2008). All or any of those animals could have been a social identifier, an offering for the afterlife, or the debris from a funeral feast. As archaeologists have become more aware of the symbolic social role of feasting in past societies, the recognition of feasting debris has become an important topic in zooarchaeology. Attention has returned to shell middens, now seen as having had a social or even ceremonial function. Care is needed here: One researcher’s food debris is another’s ritualized middening and yet another’s taphonomic palimpsest. None of those interpretations is necessarily wrong, and each of them may be the most useful interpretation given different research agendas.

Although the process has been a slow one, zooarchaeology has established itself as a significant discipline with a role to play in our

understanding of the human past. The recent development of “social zooarchaeology” reflects a desire to see animals as having played more than a subsistence role in past societies, even if the meaning of the term is currently rather fluid, and some argue for a recognition of animals as cultured entities with agency in the construction of human societies. Beyond archaeology, conservation science and neozoology have become aware of the importance of long-term baseline data on animal abundance and distribution (see BIOGEOGRAPHY), emphasizing the need for valid identifications and reliable dating evidence (Wolverton and Lyman 2012). The globalization of zooarchaeology is moving the center of activity away from researchers in western Europe and North America, diversifying the cultural basis of the discipline and raising quite new and stimulating research agendas. In Southeast Asia, in particular, zooarchaeology is having a real impact on wildlife conservation by demonstrating the past range of species now seen only in fragmented refugia. Furthermore, the prevailing European/North American tradition in zooarchaeology is being challenged and altered by paradigms deriving from societies that take a quite different attitude to animals and to the understanding of their excavated remains. The future of zooarchaeology lies in reaching out globally and intellectually to take in new insights and paradigms and to disseminate the information that the discipline generates.

Zooarchaeology and Ancient DNA

ROSS BARNETT

Durham University, UK

In the seminal 1984 paper by Higuchi et al. (1984) that first showed the post-mortem survival of ancient DNA and initiated the entire field of ancient DNA studies, the authors used small scraps of muscle tissue found while remounting a specimen of the extinct quagga (*Equus quagga*). Using primitive bacterial cloning methods they showed that recognizably equine DNA sequences were still to be found within. From there, the field split into two main branches: those concerned with getting ancient DNA from human remains and those concerned with getting DNA from other sources. While the study of ancient DNA from human remains requires incredibly stringent laboratory protocols to prevent contamination, working on zooarchaeological material happily circumvents many of these issues due to lower risks associated with working on extinct species, rare specimens, and domesticates.

In the first decade of ancient DNA research, the analysis of zooarchaeological remains followed a clear pattern. When bacterial cloning methods were supplanted with the infinitely more powerful polymerase chain reaction (PCR), many groups identified species with poor taxonomic resolution and used phylogenetic methods to definitively place them within recognized lineages. During this phase, recently extinct species such as the Tasmanian tiger (*Thylacinus cynocephalus*) and woolly mammoth (*Mammuthus primigenius*) were analyzed from preserved remnants of tissue. Museums were suddenly reimagined as vast repositories of genetic information, and studies of extinct populations of living species or phylogenetic analyses of species so rare that field studies were impossible became a reality. Initial publications were conservative in nature, mostly confirming pre-existing hypotheses about relationships. The power of PCR allowed researchers

to experiment with alternative sources of DNA. In particular, the ability to extract high-quality DNA from subfossil bone, which is found in enormous quantities in permafrost regions, was a breakthrough that massively expanded the age of the material that DNA could be recovered from and opened up the Late Pleistocene as a period that could be studied through genetics. This expansion brought with it an avalanche of new questions related to population dynamics, ecological regime changes, and the nature of the megafaunal extinction.

However, at the same time, trouble was brewing. While some researchers were expanding the scope of questions that could be asked with ancient DNA within a short chronological time frame, others were simply trying to push back the age of putatively recovered DNA. Starting in the early 1990s and reaching a crisis point during the mid-decade, this singular agenda led to reports of DNA from Miocene fossils, Oligocene amber, and Cretaceous dinosaur bone. When these studies could not be reliably replicated, and further study suggested they violated the kinetics of DNA breakdown, the field lurched into a self-inflicted crisis of confidence. Trust was only recovered when a comprehensive set of guidelines were voluntarily adopted, with an emphasis on internal and external replication of results (see DNA: MITOCHONDRIAL and DNA: NEXT GENERATION SEQUENCING).

Since then, the use of ancient DNA in zooarchaeological studies has expanded considerably. Study of the phylogenetics of extinct species has become a useful tool to place unusual taxa within a standard taxonomy. Recovery of longer fragments from mitochondrial and nuclear DNA has shown definitively that traditional morphometric methods can be by turns too conservative or too radical. Good examples of this can be found in the study of New Zealand's recently extinct flightless moa (Aves: Dinornithiformes). Early work looking at variation in bones of this family vastly overestimated the number of species. Ancient DNA from well-preserved remains showed that species limits were quite clear genetically and

DOI: 10.1002/9781119188230.saseas0623

the species contained appreciable morphological variation (Bunce et al. 2009). Similarly, the effects of sexual dimorphism had not been fully appreciated and it was only through recovery of sex-linked genetic loci that what had previously been classified as two morphologically distinct species could be correctly assigned as males and females of a single species (Bunce et al. 2003). In New Zealand the abundant remains of moa have also been used to explore traditional zooarchaeological questions about diet. Moa coprolites (see COPROLITES) have been used to reconstruct browsing and grazing niches in various extinct members of this family (Wood et al. 2012). DNA extracted from coprolites has the advantage of identifying both defecator and dietary remains that are too small or too degraded to be identified at the macroscopic level.

Questions of species abundance and demography have also been addressed in moa using a combination of radiocarbon dating and microsatellite data to show that populations were not in decline before human settlement of New Zealand (Allentoft et al. 2014). This approach was first pioneered in Pleistocene Beringian steppe bison (*Bison priscus*). The region known as Beringia (modern-day Siberia, Alaska, the Yukon, and the submerged landscape of the Bering Strait) has been the focus of huge research interest. As a crossroads between the Old and New Worlds, Pleistocene Beringia was a dry steppe grassland subcontinent with a fauna of woolly mammoths, woolly rhinos (*Coelodonta antiquitatis*), cave lions (*Panthera spelaea*), hyenas (*Crocota crocuta*), bison, horses (*Equus ferus*), and other species. The remaining areas within the permafrost zone provide a paleoenvironmental archive of vertebrate remains that allow the exploration of the transition from the Pleistocene to the Holocene. The permafrost conditions ensure that DNA is well preserved and remains of bison and other megafauna are abundant. Using combinations of radiocarbon dating and mitochondrial data, and employing coalescent theory (which states that genetic diversity varies in proportion to effective population size), it has been possible to graph effective population size (N_e) for a number of extinct and extant Beringian megafauna. Paradoxically, the data have shown that while some species (mammoth, rhino, horse) did not appear to go through a population bottleneck at

the end of the Pleistocene, bison went through a sharp decline at the beginning of the Holocene, yet recovered to become the most abundant large mammal in North America by the Late Holocene (Lorenzen et al. 2011).

Large-scale studies of population change necessarily rely on huge datasets consisting of hundreds of well-dated sequences with accurate provenance. The number of taxa for which this is possible are few, but even with smaller-scale datasets, vital information on population movement can be gleaned. Carnivores tend to be found at low density in ecosystems and are correspondingly rare in the fossil record. Nonetheless, they are often of major conservation concern and have been intensively studied using modern genetic analyses. A classic case is that of North American brown bears (*Ursus arctos*) and polar bears (*Ursus maritimus*). Until recently, brown bears were classified into static phylogenetic lineages, with an implied long history of separation and with polar bears nestling within the diversity presented by brown bears. Analyses of ancient bear remains have exploded this view of phylogeography, showing that various intraspecific lineages have been highly dynamic and wide ranging, sometimes retreating to refugia, other times expanding outwards and even hybridizing with related species (Barnes et al. 2002).

Despite the place that large-scale studies now hold within ancient DNA there is still scope for singular, well-preserved specimens to contribute. In these cases, deep sequencing (i.e., high-coverage nuclear genomes) of one or a few specimens can give as much information as shallower sequencing (i.e., mitochondrial DNA, or single locus) from scores of specimens. A good example of this has come to the fore with the development of next generation sequencing technologies that allow in-depth recovery of ancient genomes with high coverage. First pioneered in cave bears, the high-throughput systems allow access to nuclear genomes, including protein-coding genes that influence the phenotype and autosomal markers that give information on population history (Noonan et al. 2005). Since each gene in a diploid genome can contain two alleles it is possible to estimate how long ago those alleles diverged from each other. By comparing the alleles of many hundreds of genes from a single genome, it is possible to reconstruct in

a timeline where alleles converge, which corresponds to periods of low effective population size. This approach has been used in studies of Pleistocene horses, confirming that climate acted as a major driver of population change in the horse (Orlando et al. 2013). Alternatively, the effects of single genes can be analyzed. One of the first to be investigated, MC1R, is involved with coat color and has been sequenced from extinct mammoths, horses, and other taxa (Römpler et al. 2006). MC1R codes for a cell membrane receptor that when stimulated switches between production of red-yellow pheomelanin and brown-black eumelanin. Loss-of-function mutations are well known in modern species and lead to a pale/red phenotype in living animals. This ideal one gene>one protein>phenotypic effect cascade is perfect for studying ancient and extinct remains, allowing us to say something definite about the appearance of animals that is not preserved in the fossil record. Typing of MC1R in fossil mammoths has shown that there was coat-color variation: Some mammoths were dark-colored and some were perhaps blonde (Römpler et al. 2006).

The intersection of zooarchaeology (see ZOOARCHAEOLOGY) and ancient DNA has given us great insight into the process of domestication (see DOMESTICATION). Using ancient DNA it has been possible to test hypotheses about relationships between wild ancestors and domesticates. Going further, work has also used phylogeography to look at domestication at the population level: identifying regions where domestication may have taken place based on the genetic signatures of wild ancestors compared to modern domesticates and commensals. As human groups often took domesticates with them as they moved, signals of that movement can be found in the genetics of ancient remains. While humans are in general genetically uniform, their commensals and domesticates tend to contain a strong signal of regional origin, reflecting histories of expansion and contraction (Dobney and Larson 2006). These signals can be used to identify focal origins for human migrations, routes taken, and even timescales. A good use of this has been with domestic pigs (see PIGS), where multiple centers of domestication have been identified, including in the Near East, and it has been possible to track the introgression of Near-Eastern domestic pigs into Neolithic Europe and hybridization with

autochthonous wild boars (Larson et al. 2007). Ancient DNA therefore not only gives access to the progress of domestication but also provides insights into the process itself.

At the forefront of ancient DNA are new laboratory techniques that allow researchers to circumvent many of the problems traditionally associated with ancient remains. Poor preservation, modern contaminants, and co-extraction of inhibitors have all stymied ancient DNA analyses of important specimens and sites. New methods using bait RNA molecules to fish out surviving endogenous sequence show great promise in greatly expanding both the range of materials that can be accessed and the maximum age of remains from which DNA can be recovered. Researchers are also experimenting with alternative sources of genetic information including eggshell, soil, hair, parchment, and many other zooarchaeological remains.

Zooarchaeology and Stable Isotopes

RICHARD THOMAS
University of Leicester, UK

HOLLY MILLER
University of Nottingham, UK

Stable isotope studies have become commonplace in archaeological investigations of human health, diet, and mobility, often underpinned by small comparative studies of associated faunal material. In recent years, the value of studying the isotope data of faunal materials in their own right has been recognized, allowing for detailed research into animal diets, changes in animal management, mobility, environment, and procurement, and what this may mean for human–animal relationships in the past (see ZOOARCHAEOLOGY).

The application of isotope geochemistry to studies of archaeological animal remains initially employed stable carbon isotopes, followed by combined stable carbon and nitrogen studies of bone collagen, to benchmark past human diets (see DIET AND CARBON ISOTOPES and DIET AND NITROGEN ISOTOPES). Small numbers of comparative samples tended to be drawn from a limited range of species with little or no appreciation that the study of the animals themselves could be of interest, either their populations or as individuals.

More recently, a suite of other biochemical isotopes extracted from archaeological animal remains (e.g., oxygen, sulfur, and radiogenic strontium) have been shown to offer enormous potential for disclosing critical aspects of human–animal interactions in the past: tracking the movement of animals at different scales, understanding animal diet and management, reconstructing their past environments, and revealing the complexity of culturally embedded social relationships. This entry uses carefully selected case studies drawn from recent

scholarship to explore each of these themes in turn and reflect upon the benefits and challenges.

Mobility

While not stable, radiogenic strontium isotopes are effective for characterizing human and animal mobility. $^{87}\text{Sr}/^{86}\text{Sr}$ concentrations vary according to local geologies; strontium isotope variability in bedrocks gives rise to soils that preserve the source geochemistry. Plants growing on these soils take up these local strontium signatures and pass them up through the food chain. Comparison of strontium ratios in tooth enamel with strontium ratios that have been mapped geographically thus affords the opportunity to track an animal's location as each tooth formed. Similarly, stable oxygen isotopes can be used to track the movement of animals through differential rainfall patterns and temperature gradients, which, in combination with strontium analysis, can refine where an animal was born and the locations in which it lived or was kept, before it became part of the archaeological record.

At Fishbourne Roman Palace in Sussex, the United Kingdom, for example, first-generation imports of fallow deer (*Dama dama*) were identified through isotope analysis. The strontium isotope ratio from a mandibular first molar dated to the first century CE indicated that it originated outside Britain. The strontium values from the second and third molars from this individual, which form later in life, exhibited a local signature. This strongly suggests that this deer was transported to England during the first year of life. Complementary analysis of oxygen isotope values from the same tooth reveals that the local signature equates to a warmer and drier location, likely the central or western Mediterranean, corroborating zooarchaeological evidence for the location of established breeding populations of fallow deer. Follow-up ancient DNA analysis (see ZOOARCHAEOLOGY AND ANCIENT DNA) mapped the specimen as genetically closer to Italian rather

than Turkish populations, suggesting a European introduction to Britain (Sykes 2014, 94).

Strontium analysis has also been used effectively to explore intra-national movement of animals. This was ably demonstrated at the mid-third millennium BCE causewayed enclosure at Durrington Walls, Wiltshire, UK (Viner et al. 2010). This evidence indicated the movement of cattle from multiple locations within Britain, carrying important implications for the mobility of people, the purpose of this type of site, and the nature of human–cattle relationships within Neolithic Britain.

In addition to the movement of living animals, stable isotope analysis has been used to reconstruct supply networks through the analysis of deadstock. An illustrative case study is provided by Barrett et al. (2011). Here, investigation focused on sourcing cod (*Gadus morhua*), which increased in frequency in northern and western Europe at the beginning of the tenth and eleventh centuries CE: part of what has been coined the “fish event horizon” (see DEEP-SEA FISHERIES). Based on the principle that stable carbon and nitrogen isotopes differ across marine regions due to variations in the length of the food chain, water temperature, and salinity, analysis of archaeological cod remains was used to distinguish local procurement from longer-distance transportation of preserved fish. The results suggested that consumer pressure from urban areas prompted the development of deep-sea fishing further afield on an almost industrial scale, because local fishing grounds were unable to meet demand.

Diet

While the isotopes of carbon and nitrogen can be used to reconstruct animal mobility (Barrett et al. 2011), they are more commonly employed in the analysis of animal diets. The ratio of the heavier to the lighter isotope ($^{13}\text{C}/^{12}\text{C}$ or $^{15}\text{N}/^{14}\text{N}$) varies across terrestrial food webs (Figure 1). Carbon isotope values are primarily influenced by the differential uptake of carbon by plants in photosynthesis, and can be used to distinguish diets based on C_3 or C_4 plants, marine, or terrestrial foods. Subtle variations in plant $\delta^{13}\text{C}$ occur in response to environmental factors such as light intensity,

aridity, rainfall patterns, temperature, elevation, and salinity. Nitrogen isotopes ($\delta^{15}\text{N}$ values) are influenced by the processes of nitrogen fixation and loss in soils, and their uptake by plants. The $\delta^{15}\text{N}$ value is then elevated by 3–5‰ at each trophic level: thus, plants have depreciated values relative sequentially to herbivores, omnivores, and carnivores; pre-weaned mammals, which effectively “consume” their mothers, are also positioned at a higher trophic level. Variability in the $\delta^{15}\text{N}$ of animals occurs in response to manuring of feed crops, growth rate of the animals, starvation, and environmental factors such as temperature and aridity. The uptake of isotopes of carbon and nitrogen from dietary sources, as differentiated by these factors, is preserved in protein-rich corporeal structures such as bone collagen, hair, skin, nails, horncores, and antler, which are in turn differentially preserved in the archaeological record (see FORMATION PROCESSES).

The analytical utility of dietary stable isotope analysis of faunal remains is apparent in a study of caprine and cattle material from the Early Neolithic (eighth–ninth millennium BCE) site of Aşıklı Höyük in Anatolia (Pearson et al. 2007). Here, a study of the bone collagen carbon and nitrogen isotope values countered the zooarchaeological interpretation that the domestic status of the animals was “unclear.” In essence, the isotope study showed that the sheep and goats had tightly clustered and overlapping values, indicating a common dietary source, close confinement, and management. Conversely, data for the cattle showed that these animals were free ranging, sourcing their diet from a variety of environments, indicating they were unmanaged and likely wild.

In contrast to the study at Aşıklı Höyük, stable isotopes can provide independent evidence to support interpretations drawn from zooarchaeological analysis. At Dudley Castle, West Midlands, UK, the animal bone evidence indicated a rapid change of pig management during the fourteenth century CE, testified by a decrease in numbers, increased body size, and a higher proportion of neonates (Hamilton and Thomas 2012). Stable isotope analysis of carbon and nitrogen was applied to establish whether there was a simultaneous change in pig diet. Analysis revealed no change in $\delta^{13}\text{C}$ values, but a significant decrease in ^{15}N across the population

Figure 1 Scatterplot of typical carbon and nitrogen stable isotope values for humans and animals by dietary group. Isotope ratios (δ) are reported as parts per mil (‰) relative to international standards PDB AIR.

in the later fourteenth century, in contrast to the pattern observed for fallow deer and cattle, which did not change in this period. This altered pig diet is consistent with the consumption of legumes, or decreased consumption of microfauna and/or fungi, resulting from a new management strategy, likely sty farming (Hamilton and Thomas 2012).

Management

As the above case studies demonstrate, changes in dietary stable isotope values can reveal changing management practices in the past. Zooarchaeologists have long been interested in identifying the season of occupation/use of sites and resources to better understand human mobility and subsistence practices. Isotope biochemistry has been used to elucidate these patterns further, as well as to show how the animals themselves were kept. For example, sulfur isotopes have been used to show that, once established, the breeding populations of fallow deer at Fishbourne Roman Palace (see above) were moved. The site, close to the south coast of Britain, is part of an estuarine

environment that is affected by proximity to the sea. Sea-spray-affected graze can alter sulfur isotope values because marine water $\delta^{34}\text{S}$ is higher than that in terrestrial and freshwater environments. While some fallow deer had elevated $\delta^{34}\text{S}$ values, others did not, indicating that deer management practices and the location of the Palace's deer park changed through time (Sykes 2014).

In a study of resource management, oxygen isotope ratios ($\delta^{18}\text{O}$) have been recorded from incremental growth rings in cod otoliths recovered from Mesolithic sites from the mid-fifth millennium BCE in southern Norway in order to establish the time of fish capture, and therefore the season of use, of two sites: Skoklefall and Skipshelleren (Hufthammer et al. 2010). The $\delta^{18}\text{O}$ values of the final rings of growth, those at the edge of the otolith which is the material deposited at the time of fish capture, were consistent with cold water temperatures, thus establishing that the sites were in use during the late winter or early spring (Hufthammer et al. 2010).

As the example from Aşıklı Höyük shows, stable carbon ($\delta^{13}\text{C}$) and nitrogen ($\delta^{15}\text{N}$) isotope analysis has the potential to elucidate dietary

regimes, which, in turn, have been used to disclose husbandry and foddering strategies. In Britain, this approach has been used to examine the fauna of two major midden sites: at Llanmaes in South Wales and Potterne in Wiltshire (Madgwick, Mulville, and Stevens 2012). Exceptionally wide-ranging results for pigs, particularly in terms of $\delta^{15}\text{N}$ values, indicate diverse foddering strategies: During the British Neolithic (third to fourth millennium BCE), pigs fed in woodlands, but by the late Iron Age (last two centuries BCE) this was supplemented by the incorporation of household waste. Similarly, caprines appear to have been raised on land subjected to different degrees of manuring, representing differing household or community management of crops and livestock. These local and even household management signatures in the animals belie the idea of specialist and/or large-scale food producers in the late Iron Age (Madgwick et al. 2012).

Environment

Broader patterns of environmental change can be revealed through the analysis of stable isotopes from archaeologically recovered animal remains. Evidence from nine archaeological sites situated on salt-marsh land in Belgium, for example, have highlighted how the diets of domestic herbivores were transformed by the changing coastal landscape between the Roman and late medieval periods (first to fifteenth century CE) (Müldner, Britton, and Ervynck 2014). Bulk collagen carbon and nitrogen data showed how variations in the animals' diet at different sites over time were consistent with shifting animal management and environmental change. Coastal exploitation in the Roman period appears to have been limited and seasonal, whereas early medieval herbivores grazed coastal areas all year round, with carbon and nitrogen values showing an increased marine influence. In the late medieval period, sheep and cattle carbon and nitrogen isotope values from coastal and inland sites become more consistent, indicating disappearance of coastal marshes (Müldner et al. 2014).

Human–animal relationships

Most of the isotope studies of zooarchaeological materials described above focus attention on animals as units of economic production, typically at the scale of a time-averaged “herd.” This is as much a reflection of prevailing intellectual concerns, conditioned by contemporary perceptions of animals, as it is by the reality of the lived human–animal experience in the past. However, there are a growing number of zooarchaeologically informed stable isotope studies that recognize the cultural role that animals played in human society, identifying the need to consider both agency and individuality.

To take one example, a number of human burials from the Avar period cemetery of Wien-Csokorgasse, Austria, contain socially stratified grave goods, frequently including chickens. Zooarchaeological investigation reveals that the offerings were not random; women were buried with hens, while cockerels were interred with men, with the longer spurs occurring in the graves of relatively higher-status men—indicative of a society where cockfighting was an important signal of masculine identity (Kroll 2013). To investigate the proximity of the human–chicken relationship, samples of the humans and chickens were compared through carbon and nitrogen isotope analysis. Preliminary results suggest direct correlations between the $\delta^{15}\text{N}$ values of the humans and the chickens interred with them. This parallel indicates that the protein content of the diets of humans and chickens buried together mirrored each other, and that the human–chicken relationship was close in life (Sykes 2014, 134): Individual chickens belonged to and were buried with individual members of society.

Dogs are often included in dietary isotope studies of humans as their omnivorous eating habits mean that they are perceived as good proxies for human populations. Few studies focus on the role of dogs as individuals; yet, one of the strengths of isotope applications is that they can identify and offer important information about individual animals. An illustrative example is provided by Mackinnon (2010) who describes a small, round-skulled dog (comparable in morphology to the Maltese toy breed) buried alongside a 10- to 15-year-old child from Roman

Carthage, Tunisia. The dog exhibited a range of skeletal pathology, including congenital hip dysplasia, pronounced degenerative joint disease, and extensive tooth loss. Despite a permanently dislocated hip and crippling arthritis, which would have doubtless affected the animal's mobility, the dog had survived to an advanced age, suggesting that it had been cared for throughout its life. Dietary stable isotope analysis certainly supported this view: The dog had one of the highest $\delta^{15}\text{N}$ values recorded from Roman sites in the Mediterranean, indicating a diet unusually rich in protein.

Using $\delta^{15}\text{N}$ values as a broad-brush indicator, Sykes (2014) demonstrated shifts between human and dog diets through time in Britain, effectively indicating the proximity of the human-dog relationship in different cultural periods. In the Neolithic, Iron Age, and Roman periods, dogs and humans appear to have largely consistent diets, containing similar amounts of protein, thereby suggesting a commensal relationship. In contrast, during the Mesolithic, when dogs are thought to have been domesticated, and the Anglo-Saxon period, there is greater dietary spacing between dogs and humans, indicating that human-dog relationships were less entwined.

Traditionally, zooarchaeological research has focused on themes of diet, economy, and "ritual;" however, zooarchaeological theory and practice are being increasingly influenced by engagement with ideas emerging from the field of animal studies. Research inspired by these ideas emphasizes the agency of animals and the importance of the social relationships between people and the animals with whom they interacted. The case studies presented above demonstrate the complementarity of stable isotope and zooarchaeological approaches for addressing key questions about the cultural and socioeconomic role of animals in the past at multiple scales: from time-averaged populations to individuals. Carbon and nitrogen stable isotope analysis of animals provides a unique source of evidence concerning animal diet, but can also complement zooarchaeological and other sources of evidence for changes in animal management, environment, and procurement. Strontium, oxygen, and sulfur isotopes can be used to enhance understandings of animal management and environment,

and can uniquely disclose patterns of mobility in a manner that traditional zooarchaeological evidence cannot.

Interpretation is not always straightforward, however. Many factors affect the uptake of various isotope concentrations by plants, animals, and humans alike, and it is important that as much of this information as possible is understood prior to interpretation. Certainly, the selected case studies highlight the importance of grounding zooarchaeological and isotope studies in broader environmental and cultural contexts in order to interpret human and animal behavior. The use of isotope studies thus promotes a general need to better understand the holistic archaeological record, taking into consideration ecological, physiological, and osteological factors that affect both the taphonomy of samples and the reliability of isotope data, thereby increasing our knowledge of the human past as a whole.

Aerial Photography

MARTIN J. F. FOWLER

Independent Aerial Archaeologist, Winchester, UK

The interpretation of photographs taken from an airborne platform, also known as aerial archaeology, represents one of the most important advances in archaeology in the twentieth century. Combining the innovative advances of aviation and photography, one of the first aerial photographs (APs) of an archaeological site was taken when Lieutenant P. H. Sharpe photographed Stonehenge, England, from a war balloon in 1906. The First World War gave aerial photography a great impetus as both sides urgently needed intelligence on each other's activities, as well as improvements to their mapping of the battlefield. In addition to features of military interest, many new archaeological sites were discovered, and the value to archaeology became recognized. In 1917, German military aviators undertook photography of archaeological sites in Sinai, and in the same year Lieutenant Colonel G. A. Beazeley photographed the ruins of the city of Samarra in Iraq, as well as the network of ancient irrigation canals, watercourses, and settlements.

By the 1920s, the use of APs for archaeology began in earnest with the work of O. G. S. Crawford in England and Père A. Poidebard in Syria who both recognized the great value of aerial reconnaissance. Poidebard's work in Syria was mainly concerned with the Roman Empire's eastern desert frontier and a similar pioneering investigation was later made in Jordan and Iraq by Sir Aurel Stein just before the start of the Second World War.

Crawford's work mapping archaeological sites in England seen on Royal Air Force photographs was ahead of its time and his classic campaign of photography with Alexander Keiller, heir to the famous firm of Dundee-based marmalade manufacturers, aroused general interest with the publication of their book *Wessex from the*

Air (Crawford and Keiller 1928). Encouraged by Crawford's work, Major G. W. G. Allen began work in the Oxford region of England where he discovered a huge number of previously unknown archaeological sites that were revealed by marks in crops growing in farmland.

The Second World War brought a further increase in military aerial reconnaissance and presented archaeologists like J. S. P. Bradford with opportunities to take forward their academic interests while working on the interpretation of APs. Bradford made important discoveries in Italy and Yugoslavia, in particular the extensive crop marks found in parts of Apulia, which he subsequently published in his book *Ancient Landscapes* (Bradford 1987). Following the end of the war, the appointment of Professor J. K. St Joseph as Curator in Aerial Photography at Cambridge University established the first professional post in the subject and recognized the full potential of aerial photography for archaeology.

Today, APs for archaeological use are mainly taken from a light aircraft using hand-held cameras. The resulting photographs are oblique views of the landscape, although vertical APs taken by specialist aircraft and cameras, as well as unmanned drones, are also used. The advent of affordable high-quality digital cameras has meant that traditional black-and-white (panchromatic) and color films are now being replaced by digital photographs that have the benefit of being able to be transferred to the digital environment without the need for scanning of prints or negatives. False-color infrared films have also been used in the past but with mixed results as their sensitivity to over- or under-exposure made them difficult to use in the air.

Whilst oblique APs are relatively cheap to acquire, they are selective in nature, and are usually taken of sites observed by an archaeologist in the aircraft, or as seen on previous AP sorties, and hence cover only a small fraction of the landscape below. Vertical APs are more expensive and usually result from nonarchaeological surveys, but can provide comprehensive coverage

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0007

of relatively large areas of a landscape. Both approaches have their advantages and disadvantages: Vertical photographs tend to be taken from a single pass over the landscape at a set altitude and provide overlapping cover giving stereo pairs, whereas oblique photographs can be taken from a variety of angles and altitudes around a site to take advantage of lighting conditions as the aircraft circles overhead. Oblique photographs are generally easier to view and interpret, and are good for pictorial effect and perspective, but require the use of specialist software in order to be transformed to a plan view. Once rectified and georeferenced to a coordinate system, both oblique and vertical photographs can be transcribed and integrated with other archaeological and landscape information in a geographical information system (GIS) to produce a comprehensive digital map of the archaeology of an area.

The types of archaeological sites that are apparent on APs are generally of two forms: Sites on which there are standing remains, and sites that have been levelled by agriculture (Riley 1987). They are usually described in the way in which the features are revealed, such as *earthworks*, *crop marks* or *soil marks*, rather than by the physical form that they represent. Thus *earthworks* represent features that can be seen in relief, such as banks and upstanding archaeological features, and are usually present in the form of highlights and shadows depending on the lighting at the time the photograph was taken. Where the color of the surface is relatively uniform, the shadows cast by low sunlight can provide most information. In arid regions where there is little vegetation, differences in the color of the stones of an archaeological feature and their surroundings may be apparent on aerial photographs. Low earthworks may also be revealed by drifting snow, as well as by differential flooding of the land.

Crop marks result from changes in the growth and color of crops on cultivated land when buried features either increase, or decrease, the availability of moisture and nutrients. Being sensitive to a range of factors including the type of crop and the date of sowing, the type of soil, and the weather during the growing season, crop marks can be transient in nature, standing out strongly one year, yet barely or not at all visible, the next.

Deep-rooted plants such as cereals like barley and wheat, and some root vegetables, are affected considerably by differences in the depth of soil and therefore are particularly conducive to the development of crop marks.

Areas of better crop growth generally result from deeper soil over filled ditches and pits where the conditions for growth are enhanced. Typically they are greener in color, taller and of a denser growth. Areas of poorer growth generally result from shallower soil over buried walls or other inorganic features where the plants tend to be stunted, paler green, and less dense in growth. Whilst grass is less responsive than cereal crops to differences in the underlying soil, differences in growth may occur in very dry weather with underlying features becoming apparent as *parch marks* on APs.

Soil marks are mostly visible on photographs of bare soil on cultivated land in winter months and show the presence of buried ditches, banks, or foundations through soil color variations. Generally, buried ditches appear as dark lines where material from their infill has been brought to the surface by ploughing, whereas the remains of levelled banks and mounds usually make lighter-toned marks. Differential moisture retention may also give rise to *damp marks* which fade when the soil dries and whilst many may have little archaeological meaning, others may provide an indication of buried features. Photographs of soil marks require careful interpretation as many natural features can influence soil color.

The considerable power of aerial photography for landscape survey can be seen from Palmer's (1984) seminal study of the landscape surrounding the Iron Age hillfort at Danebury in southern England. By using several thousand vertical and oblique APs he was able to map the archaeological features that had mostly been flattened by ploughing in a 175 square mile (450 square km) area around the hillfort and showed that it was surrounded by a complex agricultural landscape. At least eight other hillforts, over 100 farming enclosures and settlements, 7,000 acres (3,000 hectares) of ancient fields, 600 round barrows and ring ditches, of which 187 were newly discovered, and some 150 miles (240 km) of linear ditches were apparent on the APs. Through morphological analysis and the findings of the excavation of some of the settlement sites, he

was able to develop a series of period maps that documented the evolution of the landscape from the Neolithic to the end of the Romano-British period.

The Cold War continued the evolution of aerial photography through the development of photoreconnaissance satellites capable of providing high-resolution photographs from low earth orbit. In the 1990s, photographs from the Russian space program became commercially available and a study of a KVR-1000 photograph covering the environs of Stonehenge showed that it was broadly comparable with conventional medium-scale vertical aerial photography and capable of showing a range of upstanding and plough-leveled archaeological features (Fowler 1996). The declassification in 1995 of over 800,000 photographs from the US CORONA program provided public access to an extensive archive of previously highly classified high-resolution satellite photographs at very modest cost. Acquired between 1960 and 1972, and with near global coverage, the archaeological potential of the photographs was promptly demonstrated by Kennedy's (1998) study of the Greek and Roman cities of Samosata and Zeugma in modern Turkey. Since then, CORONA photographs have been used extensively, particularly in areas where conventional aerial photography is either prohibited or impractical, with Ur's (2010) mapping of over 3,700 miles (6,000 km) of premodern trackways in the vicinity of one of the largest Bronze Age sites at Tell Hamoukar in northern Mesopotamia demonstrating the huge potential of this resource. In 2002, further US intelligence satellite photographs were declassified including photographs from the GAMBIT program. Whilst GAMBIT had a higher resolution than CORONA, it was targeted on specific military and other installations in the former Soviet Union and China thus limiting its wider archaeological utility, but making the photographs particularly suited to studies of Cold War material culture.

High resolution images acquired by commercial satellites using panchromatic and multispectral sensors are now readily available and have been shown to have clear archaeological utility. The free availability of these type of photographs through virtual worlds such as Google Earth has generated a wider public interest in aerial archaeology and presents the potential for

the use of crowdsourcing to locate and identify features on archival images. When combined with archival photographs, recent satellite images can be used to monitor the condition of archaeological sites over time, particularly in areas of conflict identifying where areas of looting and damage can be identified.

The worldwide archives of millions of historical aerial and satellite photographs represent a considerable and largely untapped resource for archaeological survey and landscape analysis. With increasing online access to archives of digitized aerial and satellite photographs, and the development of GIS to aid their interpretation and analysis, new and unique opportunities are presented for the discovery of archaeological sites that have been destroyed through intensive land use and development, and for the development of new insights into the character of ancient landscapes.

Archaeological Videography

COLLEEN MORGAN

University of York, UK

Archaeological videography visually communicates some aspect of archaeological research and is either authored by archaeologists or through close consultation with archaeologists. Archaeologists have been using movies to document, explain, and publicize their research since the earliest days of cinema. These early films depicting archaeological research were often made by news agencies, particularly in the United States, United Kingdom, and other countries in western Europe and typically showed archaeological expeditions in far away “exotic” locations such as Egypt or Palestine. Several online archives including Europeana, Movietone, the British Pathé News Archive, and the Associated Press Archive feature excavation footage dating from the 1920s. This footage is of excavations in both local and foreign locations; the nonlocal excavations would often contain establishing shots that showed fantastic landscapes, locals in traditional attire acting as field staff on the excavations, and site directors framed as authoritative explorers in military-esque garb. Local archaeological excavations were also featured in much the same way, with an authoritative male archaeologist addressing the camera or giving visitors a tour while laborers excavated behind him. These tropes have reappeared throughout the history of archaeological videography, and reinforce the understanding of archaeological investigation as searching for treasure with triumphalist, nationalistic undertones.

In addition to appearing in front of the camera, archaeologists have long collaborated with documentarians to create film productions about archaeology and the past. Notably, in 1944 the Ministry of Education in the United Kingdom commissioned Jacquetta Hawkes to create a film on British prehistory. The making of this wartime

film is documented by Christine Finn (2001) who notes the prevalence of the narrative of invasion in the context of prehistoric Britain. Similarly, in the early 1950s in the United States, the Archaeological Institute of America produced a series of documentaries about the past. Ray Garner, the filmmaker in charge, was particularly concerned with verisimilitude in past violent action and used naturalistic visual metaphors such as thunderclouds sweeping over the mountains to depict ancient battles.

While archaeologically themed broadcasting began on television in the 1930s (Perry 2017), the programs *What in the World?* in the United States and *Animal Vegetable Mineral?* in the United Kingdom, which had scholar-contestants try to identify various artifacts, further popularized the format in the 1950s. Building on the success of these programs, archaeological documentaries became a mainstay of British and American television. By the 1970s there were enough archaeological documentaries to warrant a round of publications regarding useful titles for teaching archaeology, followed by a book of film reviews, *Archaeology on Film*, published by the Archaeological Institute of America in 1983. At the same time, changes in visual media technology such as the move from 16 mm film to videocassette and the proliferation of videocassette recorders (VCRs) made video production and distribution less expensive, increasing the availability of archaeological films and broadening nonspecialist access to production. Though systematic video recording was mentioned in the early 1990s as useful in archaeological excavation for a more complete visual record and its use considerably elaborated on sites such as Çatalhöyük (Tringham, Ashley, and Quinlan 2012), the time required to sort and edit film made extensive recording impractical. Much of this informal excavation footage is now unavailable as a result of format obsolescence and lack of formal archival strategies. Even as participation in both formal and informal video production increased, there was very little critical examination of archaeological film until Angela Piccini's (1996)

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0031

discussion of the construction of Celtic people in documentaries wherein she questions the audience for archaeological films and the construction of a pan-European Celtic warrior aristocracy.

The technological shift to the use of digital media for filmmaking in archaeology has had a profound effect on authorship, content, quantity, production, and distribution of archaeological knowledge (Morgan 2014). Smartphones have become more popular, capturing relatively high quality archaeological images, and video has moved from a specialist role on archaeological projects to a ubiquitous exercise regardless of the position of the participant on site. Paired with the wide distribution available on social media, videos made by students can rapidly eclipse formal publications in terms of the dissemination of information about an archaeological project. Accordingly, the quantity of available online archaeological footage has rapidly increased as distribution of current media is uploaded alongside the growing collection of archival footage. As a result, archaeological movies made by professional documentarians in collaboration with archaeologists can be viewed alongside those made by students with smartphones or even those made to advance pseudoarchaeological claims, with little to distinguish the authority of the author.

There have been some efforts to collect and distribute authoritative archaeological films on dedicated web pages such as Past Horizons and The Archaeology Channel; the latter also hosts an annual film festival in the United States. There are several other annual and semiannual archaeology film festivals, such as AGON: International Meeting of Archaeological Film of the Mediterranean Area, Arkhaios Cultural Heritage and Archaeology Film Festival, CINARCHEA: Festival du Film d'Archéologie d'Amiens, FICAB: International Archaeological Film Festival of the Bidasoa, International Festival of Archaeology Films, Nyon; Festival International du Filme d'Archeologie de Besançon, ICRONOS: Festival International du Film Archeologique de Bordeaux, International Archaeology Film Festival in Split, KINEON: International Archaeological Film Festival of Brussels, and Rassegna Internazionale del Cinema Archeologico di Rovereto. In addition to these film festivals, there

are often short films shown at archaeological conferences.

Though the technology available for making videos has changed over time, genres of filmmaking within archaeology have remained relatively static. Most archaeological videos used to teach archaeology or for public outreach are *expository*; these hearken back to the old newsreels as they are didactic, with authoritative “voice-of-god” narration, expert “talking head” interviews interspersed with action from “on location” shots that follow narratives of discovery with soundtracks laden with “traditional,” flute or drum-heavy music. While these are the most common and clichéd form of archaeological videography, they remain useful for straightforward storytelling and are accessible to broader audiences. The *direct testimonial*—sometimes referred to as a “video diary”—is an account of current finds and conditions on site. Archaeological video diaries are likely to have derived from the practice of site tours, during which the archaeologist would relay information about the stratigraphy and any interesting finds to a small audience. There are a handful of *impressionistic* archaeological videos, which explore the space between art and archaeology. These videos celebrate subjectivity and lack the authoritative voice-overs and didactic structure of expository film, but can be frustrating to audiences who expect tidy narratives about the past. Finally, *phenomenological* films grant the viewer the gaze of an archaeologist by filming at eye level and recording the sensory components of archaeological fieldwork in a single, continuous shot. This genre has increased in popularity in conjunction with smart phone cameras and social media, wherein short videos can be featured alongside static photographs. None of these genres is exclusive; some videos feature aspects of two or more of these genres.

While archaeological documentaries are still relatively conservative in content and scope, archaeological videography is an exciting and increasingly porous medium with new formats such as animated GIFs, remixes, machinima made in virtual worlds, head-mounted action cameras, video podcasts, “let’s play” video gaming commentaries, animations, and drone footage

shifting and changing how we present our interpretations of the past. These videos can be embedded within other social media platforms and viewing interfaces can stream videos in a sequence, or presented as a nonlinear series of choices to jump between topics. Though the future of archaeological videography presents a broad array of creative ways to present archaeological research, it is a threatened format and amounts to so much digital ephemera without an increased attention to archival strategies that incorporate multimedia. Helpful guidance for the preservation of digital video can be found at the Archaeology Data Service (http://guides.archaeologydataservice.ac.uk/g2gp/Video_1).

FURTHER READINGS

Augering

ANTHONY R. TRICARICO

University of South Florida, USA

Augering in archaeology has often been conflated with coring (see CORING), but each has distinct methodological advantages and disadvantages. Augering refers to the removal of a sediment or rock sample in discontinuous segments, which disturbs the overall context and (without proper methodological considerations) may hinder inferences regarding landscape structure. Coring removes sediment or rock samples in a continuous cylindrical section (Stein 1986). However, in comparison with traditional excavation methods, augering is far less destructive, and more cost and time effective. The appropriateness and feasibility of using augering or coring to test a site for future excavation or to determine the concentration of artifacts has been heavily debated within the literature. Augering was first introduced into archaeological practice around the mid-1930s as a means of collecting sediment for the relative dating of archaeological deposits. Augering has since become increasingly important in contemporary archaeological investigations to examine buried sediments, ancient depositional environments, and the structural integrity of the landscape (Stein 1986). Augering offers distinct advantages over coring, which makes it a suitable method for geoarchaeological assessments of regional landscape ecology (see GEOARCHAEOLOGY).

Archaeological research has employed augering in various fashions since its first implementation in 1935. Stein (1986) defines the initial use of augering from 1935 to 1955 as “Period I.” Augering played an important role in the relative dating of archaeological deposits during this 20-year period. Specifically, research by Louisiana State University, Department of Geography and Anthropology implemented augering as a key method in their research projects in the Lower Mississippi River Delta throughout “Period I.” These early investigations extracted

river sediments in order to date corresponding archaeological remains (Stein 1986). There was a distinct shift in methodological applications and theoretical considerations of augering around 1964. Corresponding with both the introduction of radiometric dating and the processual critique of culture-historical archaeology, the feasibility and appropriateness of using augering to test ecologically driven research questions was debated. Beginning in the mid-1960s, augering became less important as a tool for dating an archaeological site and more important as a tool to reconstruct the landscape and collect sub-surface soils and sediments. In the late 1970s, augering was also employed in exploratory investigations, which sought to determine distinct site boundaries on the landscape (Stein 1991). The post-processual critique of archaeology and the increased value of human agency in human–environmental interaction increased the usefulness and feasibility of augering in anthropological archaeology methodologies. The usefulness of augering was at the forefront of another debate in archaeological literature in the early 1990s over “research” versus “cultural resources management” (CRM) projects. Stein (1986) defines the period from 1964 until the present as “Period II,” though Schuldenrein (1991) argues that a “Period III” began around 1970 and intensified with the implementation of augering in CRM projects (see CULTURAL RESOURCES MANAGEMENT). It is clear that these arbitrary period distinctions are associated with a larger schism in the field during this period between academia and public archaeology. However, despite potentially different research questions/agendas, augering was employed in both areas of archaeology as a less-invasive (compared with traditional excavation) and cost-effective means of examining the relationship between landscape features. Landscape ecology studies have defined the current emphasis and use of augering, especially in a growing number of interdisciplinary geoarchaeological investigations. These investigations often employ augering to collect sediment samples for physical

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

© 2018 John Wiley & Sons, Inc. Published 2018 by John Wiley & Sons, Inc.

DOI: 10.1002/9781119188230.saseas0053

and chemical analysis. Sediment samples not only inform the greater geomorphology of the area, but also help socioecological research questions examining the changing human–environmental dialectic throughout the archaeological record.

A majority of archaeological investigations that employ augering as a key method, especially interdisciplinary archaeological geology projects, examine socioecological dichotomies on a regional scale. Specifically, geomorphological assessments (see *GEOMORPHOLOGICAL SURVEY*) of current landscape conditions are adopting ecological theory as a means of correlating landscape structure with the spatial patterning of archaeological deposits (Stafford 1995). The utility of augering in examining the density of archaeological deposits though has also been debated. Howell (1993) compared the subsurface artifact densities extracted from auger probes versus 1 m by 1 m test excavations. Auger probes yielded fewer artifacts than the test excavations, though this is expected due to differences in scale. Augering has been widely viewed and cast as a “pre-excavation” method or a means of evaluating the best areas to excavate in the future. However, interdisciplinary applications of augering place greater importance on its utility as a primary excavation method. Augering can be a key component in extracting the subsurface sediments and soils that inform geomorphological patterns, though distinct disadvantages have been noted (Stein 1986; 1991; Stafford 1995). Stein (1986) highlights that the key advantage of augering and coring is their ability to define both the vertical and horizontal extent of archaeological sites. However, the boundary between cultural and noncultural material is often difficult to define. Augering may also be as labor intensive as other methods (Stafford 1995), while consistently mixing subsurface material (Stein 1991), conflating the interpretative value of the data. However, the advantages outweigh the possible methodological disadvantages. Since augers lack the cylindrical tube used by coring devices, they can penetrate a greater variety of subsurface material (Stein 1986; 1991). Augers are also capable of extracting larger volumes of material quicker than other coring methods, while providing a finer control over the extraction interval. Control over the extraction interval allows augers to overcome and reduce the

hindrances of mixed material, providing an accurate picture of subsurface structure (especially across a larger regional level) (Strafford 1995; Stein 1986).

The most implemented form of augers across archaeological investigations is the bucket hand auger. The bucket hand auger is a manual variant, which is turned using a T-bar. The T-bar is connected to the auger through a simple metal pole, which may be extended to reach greater depths. Some investigations employ powered augers, though there are significantly greater costs in comparison with manual hand augers. An auger extracts samples in a helical motion by cutting into the deposit using two cutting bits, which can vary depending on the underlying subsurface geology of the soil (sand, silt, clay, etc.). As the auger is turned, the cutting bits force material into the bucket for extraction (Stein 1986). Control over the extraction interval can be as fine as 10 cm in length and anywhere from 5 cm to 12.7 cm in diameter (Stafford 1995). One of the key advantages of bucket augers is their size. They allow archaeologists to assess areas that may not be amenable to traditional excavation methods. Each individual auger probe yields less material in one probe than other traditional excavation methods, but is highly representative of its context (Garrison 2016). Only a small amount of material from each probe is necessary to conduct a variety of physical and chemical tests, providing researchers with an easier way to characterize the spatiality of socioecological dichotomies across the landscape. Overall, bucket augers also allow one to extract a large volume of material quickly and cheaply at a variety of depths by using 1-m extension bars, providing a more accurate picture of stratigraphy, geomorphology, and site boundaries than coring methods (Stafford 1995; Stein 1991; Canti and Meddens 1998). The potential maximum depth of the deposit must be considered. Additional extension bars make it increasingly difficult to extract the bucket without any contamination from upper strata. In comparison to mechanical coring, augers also do not compact the layers as some percussion drilling methods or obscure changes in soil color and texture (Canti and Meddens 1998). When extracting sediment samples, it is best to collect directly from the bucket so as to avoid any potential contamination with other soils. Once

a subsurface soil or sediment has been sampled, a fairly accurate and complete picture of the horization of the auger probe can be achieved by dumping each bucket out on to the surface in a straight line. It is important to gain a minimum quantifiable number of probes in each landform visible in the regional landscape investigation. Three or more auger probes (at a minimum) in each distinct landform are usually sufficient in a regional-scale investigation in order to determine socioecological spatial distribution. Auger probes have also been used to accurately characterize the geomorphological differences along a catena by sampling along a transect.

Augering has been applied in a variety of contemporary socioecological research projects (see ENVIRONMENT AND LANDSCAPE). For example, Whalen (1990) used auger probes to delineate and define the distribution of buried features on the landscape. Whalen (1990) demonstrated that augering is an effective means of subsurface testing across large research areas in El Paso, Texas, while also providing expectations to guide later planned excavations. Cultural resource management projects, highlighted by Schuldenrein (1991), have also successfully applied augering in various projects. Rutherford (2014) conducted a survey in northwest England using auger probes to locate peat deposits before an impending development project continued. However, interdisciplinary applications of augering have shifted from determining the spatial distribution of individual archaeological sites, to accurately determining the distribution of activity patterns on the landscapes. Subsurface soils and sediments collected in each auger probe are subsequently analyzed using a variety of physical and chemical techniques (i.e., munsell, soil texture, trace-element quantification, soil organic matter analysis) to determine the degree and extent of anthropogenic pressure placed on landscapes. The degree of human-induced environmental pressure allows socioecological research projects to evaluate the legacies of past and contemporary actions on the future of the landscape. Contemporary uses of augering in archaeology have transcended both processual and post-processual research agendas and have been incorporated as a method in projects utilizing a variety of interdisciplinary theoretical approaches. Some have argued that this line of

research is uniquely suited for archaeologists because of their understanding of a deep time scale. Past interdisciplinary socioecological research projects that have employed augering as a key method have often been concerned with evaluating how the environment impacted past societies (Stein 1986). However, recent research has reversed this theoretical approach. Research being conducted in the Caribbean has utilized auger probes to conduct a geomorphological assessment of landscape conditions to evaluate how historic landscape use is impacting contemporary environmental conditions. This provides interdisciplinary research teams with a means of evaluating the impact of environmental pressures on contemporary populations, recognizing that these pressures may be legacies of prior anthropogenic landscape exploitation. Contemporary uses of augering are helping to mitigate the pressures faced by contemporary populations utilizing a variety of anthropological, theoretical, and methodological principles. Augering since 1935 has been used in a variety of contexts, but across all research projects has provided a quick, cheap, and less-destructive alternative to traditional archaeological excavation.

Coring

DAVID A. BURNEY

National Tropical Botanical Garden, USA

Coring is the removal of a minimally disturbed vertical profile of small diameter from any sort of substrate that can be penetrated with the chosen implement. In some geological applications, this penetration can go through solid rock and deep into the earth's crust, in a search for fossil fuels, minerals, and metals. Dendrochronologists take small wooden cores, generally referred to as increment borings, for tree ring studies. Very long ice cores with essentially continuous coverage of up to several hundred thousand years have been drilled in the ice packs of Greenland, Antarctica, and even high tropical mountains. In archaeology, the coring of marsh and lake sediments has been a key to analyses of fossil pollen, spores, charcoal particles, diatoms, and many other types of evidence for past environments and human traces on the landscape.

Sediment coring undertaken by archaeologists and their paleoecological collaborators in wet, or even underwater, substrates has been used successfully, in coordination with excavation efforts, to inform regional contexts about important archaeological complexes (e.g., McNeil, Burney, and Burney 2010). At richly fossiliferous sites such as caves, coring has served as a tool for choosing, in a large archaeological site, the richest areas for excavation through techniques for relatively undisturbed recovery down to five meters or more below the water table (Burney 2002).

Coring as understood by soil scientists has also been extremely useful to archaeologists in the sampling and description of soil layers over and around a site, whether wet or dry. In landscape archaeology, scientists have mapped the full extent of large anthropogenic deposits, human middens, and extreme event sites (such as megafaunal kill sites) by coring a grid pattern over a deposit and then by recording layer descriptions that can be used to extrapolate the full extent of

the deposit in terms of depth and thickness of the recognizable layers (often marked by cultural deposits) and to obtain a three-dimensional representation. Through radiocarbon dating, cultural seriation, key macrofaunal and botanical identifications, and other stratigraphic methods, detailed archaeological studies can be made with minimal effect on the site. Care should be taken, of course, to minimize research impacts by taking only as many small-diameter core samples as is prudent and by avoiding areas likely to have a high concentration of human materials. This methodology, rather than test-pitting or more extensive excavations, can aid in the conservation of cultural resources by establishing their full extent—as well as the state of preservation of the landscape surrounding the place of interest—with the help of relatively noninvasive techniques.

An important caveat related to the direct archaeological application of coring techniques is that, by definition, they are a blind probe. Ground-penetrating radar and underwater sonar can be a useful prelude to the selection of coring sites in situations where coring is available and can work. Care should always be taken to core only very judiciously, in the vicinity of a known rich site. Still, in cases where human evidence is scattered over a landscape of interest but no suitable concentrated sites are yet known (suitable for paleoecological and archaeometric studies, for instance), initial coring can greatly aid in discovery.

Coring devices

There are many types of coring devices that have proved to be directly useful to archaeological research.

Open drive samplers are the simplest imaginable devices for taking a short core in wet or moist sediments that are not too fibrous or coarse-grained. The procedure related to these devices consists of driving a thin-walled hollow tube into a substrate soft enough to allow passage. With very soft wet sediments, the tube will go

down easily in many cases, but the challenge is to pull it up without having the mud sucked out of the bottom by the opposing air pressure or, in the case of coarse sediments such as sand, simply pulled out by gravity. A second problem is that, if the downward cutting tube hits a very compact layer (and sediments become more compact with depth particularly when they are constantly under water), the plugged pipe may drive on, but without sampling the lower layers or with only a compacted and/or partial recovery.

In some cases, capping the top of the pipe before removing it can produce enough of a pressure seal to help hold the column of material in the tube (as any child with a straw and a milkshake discovers early on). The development of improved techniques such as *piston coring* in the mid-twentieth century led to an explosion of paleoecological research in lake sediments, often with large contributions to the archaeological interpretations of background climate change and inferred human effects.

A simple device of this type for coring in the mud of lakes and marshes consists of the coring tube, mounted on a strong rod that can be used to push the tube down and extract it. Inside the tube, initially at the bottom, there is a simple piston with rubber gaskets that can make a tight pressure seal. From the back of the piston, a steel cable extends to the surface. When the coring drive starts, at the top of the sediments being sought, the steel cable is fastened securely to an anchor point on the surface. The rod system is then pushed downward into the sediment, but, if set correctly, the piston will stay at the top of the sediment column until the full drive is reached (at this point the piston is at the top of the tube and maintains hydrostatic pressure). The rod can then be drawn up and the sediment will be enclosed in the tube. The piston is removed from the top, both ends of the tube are tightly corked and capped, and the outside is labeled as to measured depth and top-bottom orientation (with care, compass direction can be recorded as well, for use with paleomagnetic research methods).

Normally these drives are taken in 1-meter increments and, with thicker sediments, another tube (and another and another) can be loaded onto the rods. At the beginning of each drive,

the piston is reattached at the bottom of the new tube and the cable is advanced to reach the desired surface, now down in a hole that needs to be refound (if under water). In any case, the hole must be entered with minimum disturbance in order to satisfactorily collect the next meter. Cores over 50 meters long have been taken by this method. In many scientific circles, this type of piston corer, so widely used in paleoecology and paleolimnology, is called a Livingstone sampler, after Daniel Livingstone of Duke University. Although Livingstone was generous in pointing out that he was not the inventor of the device, he was probably the first to demonstrate very successfully its use in lakes and marshes of many types in North America and throughout Africa; thus he initiated a global network of coring sites from hundreds of researchers that provides a unique view into the planet's geologically recent past. The addition of drop-hammer devices designed to increase the driving power of the system, of chain hoists or other extraction devices designed to raise the generally resistant tube, and of a casing pipe for rod coring in deeper water made the Livingstone standard equipment in a wide range of paleoecological projects, including many focused on questions of direct relevance to archaeologists.

Ultimately a self-triggering, rodless system suspended on a cable made piston coring feasible even at great ocean depths. The Deep Sea Drilling Project (DSDP) and other large-scale international efforts have cored the oceans of the world even in very deep water, where sediment records that go back millions of years can sometimes be reached—and, with very fine resolution, even down to annual layers, though such cases are very rare. The Kullenberg sampler piston corer has thus played a direct role in scientists' understanding of Ice Age climate cycles and their effect on the biota and on human ancestors.

Peat deposits, the decayed and compacted remnants of ancient bog surfaces, have created special opportunities for and limitations to coring that are of interest to archaeologists. From the earliest pollen diagrams published in Europe a century ago to some of the most exciting finds in human-related paleoecological research in recent years, various types of peat borers have played an important role in archaeological and

human-related paleoecological studies. Early examples were gouge corers and augers that brought up a monolith of peat by shoving down a sharpened tube, later refined by side-sampling models such as the Hiller borer and the Russian peat borer. Just as with piston samplers, there are many commercial brands and trade names that are available. A correct generic term for the Russian peat borer is D-section corer. The device, in closed position, is shoved down to the desired depth in soft viscous sediment. The T-handle at the top of the rods is turned 180 degrees to open the sampler, which scoops the sediment from the side of the corer, ideally in a smooth semicircular cut, then holds it inside until the borer is extracted. The obvious disadvantage (in some circumstances) over piston coring is that the sample must then be subsampled into clean sealable bags or vials before the corer is returned to the hole, thoroughly cleaned and now in closed position for the next drive.

Quite good stratigraphic recovery is possible, as has been shown in many recent studies involving careful dating and multiproxy analysis at close intervals (e.g., De Boer et al. 2014). One advantage is that the stratigraphy can be seen immediately and described in fresh condition—and uncompacted by using a piston to extrude a piston-core sample from its pipe, or disturbed laterally by sawing open the pipe. D-section cores are probably the best possible system, in manageable sediments, for the minimally disturbed recovery of plant macrofossils and insect parts. Work in these areas has been important in archaeology for characterizing prehuman versus anthropogenic biota on islands colonized by humans and for establishing the timing and extent of major human-induced landscape changes, such as increased burning of vegetation near a site and its effects.

A wide variety of *soil augers* have been used in archaeological studies for describing the soil context around a cultural site. A favorite one for the quick and reasonably accurate assessment of soil types, middens, and artifact scatters is a “mud-head” type of soil auger with a 2–4-inch (5–10 cm) diameter, angled steel blades at the bottom, and a cylindrical basket that catches about one foot (30 cm) of anything loose enough to come up with circular digging—including

wet (or even dry) soils, fine gravel, shell fragments, unconsolidated volcanic ash, and lithic debitage. Through careful measurement and use of color and texture charts for standardization, soils and sediments can be characterized over several hectares per day in typical field situations. Samples can be photographed and described in the field and, if they are desired, the resulting holes are refilled with marker material (clean sand or fine gravel is good for contrast). Resulting sediments can be bagged for archiving and lab analyses such as flotation for seeds and screening for plant and animal macrofossils.

Site integration

These landscape-level archaeological techniques have greatly assisted in the assessment of important sites, conservation planning, and the discovery of rich artifactual, ethnobotanical, and zooarchaeological deposits. Great strides have been made in recent years through the discovery and study of archaeological sites that can be considered truly *integrated sites*, where current methods in archaeology include the use of coring and other techniques for the recovery of background information on the paleoenvironment of the site. In practice, the ideal site preserves a wide range of materials in good condition and has only minimally mixed sediments.

Cosmic-Ray Muon Tomography

ROY F. SCHWITTERS

The University of Texas at Austin, USA

Introduction

Cosmic-ray muon tomography is a passive, nondestructive method for imaging internal structures of large objects, pyramids for example, that are opaque to illumination by light, X-rays, or radar. Muon tomography employs muons: charged subatomic particles found in cosmic rays that have physical properties quite different from light. Cosmic-ray muons continually rain down on us from the Earth's upper atmosphere, penetrating ordinary matter to well under the Earth's surface, and they can be detected and tracked to create images of the location and density of material along their paths.

Luis Alvarez (Alvarez et al. 1970) invented muon tomography in the 1960s to address an archaeological conundrum: of the large pyramids at Giza, why did the Second Pyramid built under Chephren and only slightly smaller than the Great Pyramid of Cheops, not appear to have the elaborate chambers and passageways found in the Great Pyramid? Did Chephren cleverly hide similar structures in the Second Pyramid, or did they not exist? By 1965, when Alvarez proposed to explore Chephren's pyramid with cosmic rays, the role of muons in nature was still somewhat a mystery, but their interaction with ordinary matter was well understood, and technology for detecting muons existed to determine their paths through 100 meters or so of the pyramid's limestone with precision sufficient to resolve the conundrum. Alvarez was able to conclude: "We can say with confidence that no chambers with volumes similar to the four known chambers in Cheops's and Sneferu's pyramids exist in the mass of limestone investigated by cosmic-ray absorption." It would take another quarter-century

before muon tomography was applied to geophysical research (Nagamine 1995)—to image volcanoes—and not until the early 2000s was it considered again for archaeological (Melesio 2014) and national security (Borodzin et al. 2003) applications.

The muon and other particles

The Standard Model of particle physics (Particle Data Group 2015), formulated in the decade following Alvarez's pyramid study, classifies particles of matter according to their interactions with other particles: "hadrons" interact via all recognized basic forces—the strong nuclear force, electromagnetism, and weak forces responsible for nuclear beta decay—and "leptons", which do not interact through the strong nuclear force, but do via the others. Atomic nuclei are hadrons; electrons and muons are leptons. (The Standard Model also includes "force" or "field" particles, of which the photon is the most familiar; it is the particle that enables sight and imaging.)

Atomic nuclei interact so strongly in tenuous air molecules in the upper atmosphere or limestone in a pyramid that they simply do not penetrate very far through ordinary matter. Leptons are capable of penetrating longer distances. Neutrinos are uncharged and only rarely interact with anything; they can be detected, but are hopeless for imaging. Muons are electrically charged, like electrons, and interact relatively weakly with atoms. Their interactions in matter at the high speeds of cosmic rays produce two effects important to muon tomography: (1) they scatter—deflect repeatedly and randomly over relatively small angles by electric forces; and (2) they ionize some of the atoms they encounter, slowing down slightly with each encounter. Scattering will determine the ultimate precision to which a muon trajectory can be measured, and ionization (the same mechanism that creates health hazards associated with "radioactive" materials) will eventually stop a muon, at which point it will be captured by an atom or decay,

either of which attenuates the number of muons passing through matter.

Muons are unstable, decaying to electrons and neutrinos with a mean lifetime of $2.2\ \mu\text{s}$ after their creation. The muons we use travel close to the speed of light, which, through the magic of Einstein's time dilation effect, permits them to travel many kilometers before decaying, whether in air, limestone, water, or vacuum. Cosmic-ray electrons, owing to their smaller masses (about 0.5% that of a muon's), suffer catastrophic collisions with ordinary matter, causing their energy to be dissipated within centimeters upon entering matter at ordinary density.

The point of all this detail is to highlight the fact that muons, of all the particles in the sub-atomic zoo, are *uniquely* suited for cosmic-ray tomography: they can penetrate many meters of ordinary matter, but are not so penetrating as to escape detection; they are electrically charged, enabling them to be tracked accurately by following their ionization path; and their numbers are attenuated by the total material each muon traverses, providing a basis for image contrast based on material density. Most important, Nature provides these useful high-energy particles around the clock, everywhere on Earth.

Origins of cosmic-ray muons

Muons are products of weak decays of hadrons created near the top of the terrestrial atmosphere by energetic collisions of "primary" cosmic rays with molecules of Earth's atmosphere. Primary cosmic rays are atomic nuclei accelerated to very high energies by some of the most energetic processes in the cosmos; they travel galactic distances at essentially the speed of light before encountering Earth. Our planet and all life on it is shielded from these hazardous particles by the upper atmosphere. A complex interplay between strong interactions and weak decays of the progeny of primary cosmic-ray particles created near the top of the atmosphere leads to the preponderance of muons observed in cosmic rays near the Earth's surface.

Of great practical importance to muon tomography is the rate at which cosmic rays "illuminate" objects which is quantified in terms of "muon

flux": the number of muons crossing a given horizontal area per second near the Earth's surface. At sea-level, the flux is about 200 cosmic-ray muons per square meter per second. Their average energies are sufficient to penetrate 20 m of water or 8 m of solid rock before stopping; many go much further. A typical muon will scatter by about 0.5° after traversing 4 m of rock. These key properties of naturally occurring cosmic-ray muons—flux, energy, and extent of scattering—largely determine the overall scope of the detectors needed for muon tomography.

Detecting and tracking cosmic-ray muons

Muons are detected and tracked by the contrail-like ionization they leave behind as they pass through matter. For his pyramid experiment, Alvarez used then state-of-art detectors somewhat over $3\ \text{m}^2$ in area that could track muons to 0.5° accuracy, sufficient to the task. Tons of other equipment needed to operate the detectors was hauled into the Belzoni Chamber via a narrow passageway, along with the tracking detectors. Advances in detector technology since the 1960s provide much cheaper and simpler options today. The active detector area needed for muon tomography, however, cannot be made much smaller with new technology because image quality depends on the number of muons detected, which is proportional to detector area.

Today's technologies involve rapid (few nanosecond) electronic sampling of ionization, with fine (millimeter to centimeter) spatial resolution in various media that can be assembled into the meter-scale particle tracking systems needed. Software algorithms associate ionization signals from each muon to determine the track direction and location. Parameters describing the track—two angles giving the muon's direction and two position coordinates—are stored for each muon detected for subsequent imaging processing.

The approach just outlined is followed in essentially every high-energy physics experiment conducted anywhere in the world today, including the immense detectors at the CERN Large Hadron Collider (LHC) now testing the Standard Model and searching for new phenomena. Fortunately,

detecting and tracking single cosmic-ray muons is vastly easier than reconstructing complex LHC collision events: there is only one particle to track at a time, and cosmic-ray track rates are a million times smaller than those encountered in LHC experiments.

Many choices go into the design of particle detectors. Briefly, the detectors built and tested as part of our University of Texas at Austin (UT) Maya Muon Project (Schreiner 2016), a collaboration between the UT Physics Department and the UT Center for Archaeological and Tropical Studies (Programme for Belize Archaeological Project 2016), emphasize: (1) ruggedness, to be able to operate reliably in remote locations; and (2) accuracy in tracking muons over a large angular field of view, for providing compact 3D imaging. Five detectors have been built and tested under various conditions, including an underwater calibration study. These detectors can be hand-carried and set up in various orientations in tight spaces, and operated without intervention for periods of days to months. We chose a cylindrical design, where the tracking sensors consist of three layers of 1 cm^2 cross-section plastic scintillator strips wrapped in helices on a 0.5 m diameter, 1.6 m long cylinder; the strips are sensed with optical fibers and photomultiplier amplifiers. An onboard computer determines the entrance and exit locations of muons passing through it, to an accuracy of a few millimeters. 448 scintillator strips in three cylindrical layers permit measurement of muon directions over essentially the entire open sky to better than 0.5° resolution, about the angular size of the moon. At sea-level, approximately 50 muons are recorded per second in each detector.

Four parameters—two direction angles and two position coordinates—describe each detected muon track. They are used to form an address for a large, four-dimensional array that records the muon flux in each of its 18 million cells. Our 4D track arrays can be thought of as being like pixels in a digital camera. The sizes of our “pixels” are comparable to the measurement accuracy—in direction and location—of the detector, when muon scattering is taken into account. Muon attenuation is measured by comparing numbers of muons recorded in the flux arrays for data taken with the detectors located next to a pyramid to runs recorded under a completely

open sky. Borrowing from astronomers, we describe such comparisons as “flat-fielding” the data.

To create images of muon attenuation or, equivalently, target mass density, the attenuation determined in each cell of the flux array is projected to 2D image planes of any desired size and orientation, using the track information encoded into the flux array address. Using detectors at several locations around the target to be imaged and methods of computed tomography, the 3D mass density is revealed.

The beauty of muon tomography is that track direction information, not available in conventional photography, allows examination of three-dimensional mass density projected conveniently onto two-dimensional image planes that can viewed and moved about by computer control to visualize dense regions and voids over the full volume of the target. No region of the target volume need ever be out of focus. Images from a laboratory test of cosmic-ray muon tomography are shown in Figure 1.

Additional considerations

Alvarez established practical and scientifically meaningful cosmic-ray muon tomography in the late 1960s at Chephren’s Second Pyramid. This success represented a major effort by a collaboration of experienced experimental physicists and archaeologists pursuing a clear research goal. Detector and computing capabilities have advanced substantially since then, including even an industrial base for muon imaging in specific kinds of national security applications.

Alvarez imaged Chephren’s Second Pyramid from the Belzoni Chamber, a room located near the center of the pyramid’s base connected by a horizontal tunnel to the outside. Aside from the convenience of having an existing tunnel under the site, there is no need to set up detectors directly under the space to be imaged. Given the relatively large spread in muon directions away from vertical, tracking detectors can be placed around the outside of the base of a structure of interest and still track muons passing through much of its volume, as indicated schematically in Figure 2.

Figure 1 Laboratory test of muon imaging. Four reconstructed horizontal image planes are shown from a dataset taken with two UT Maya Muon detectors operating for roughly one week. The circles represent end views of the detectors used in this test. Arrows and dashed lines indicate the locations of the respective image planes. The top image (a) shows the pattern of bricks on the top of the building, 6 meters above the detectors and separated by 3 feet of dense concrete. Planes (b) and (d) show no distinct images; they are located in empty space between the two target sets and detectors. Plane (c) shows an image of two sets of lead bricks located just above the detectors. The ones spelling “UT” stand 8 inches high vertically; the faint T is only half as high, accounting for the smaller attenuation observed.

Figure 2 Schematic view of muon imaging by placing detectors around the base of the structure to be studied, when a tunnel underneath is impractical. The relatively broad angular range over which cosmic-ray muons are observed makes such a scheme feasible. The “mayfly” patterns above the detectors are meant to indicate the regions of highest sensitivity of UT Maya Muon detectors when deployed in a vertical orientation, as shown in Figure 3.

Figure 3 UT muon detector oriented vertically at the base of a Maya pyramid, “Structure 3”, at the Programme for Belize La Milpa archaeological site in Belize (Schreiner 2016). The shed protects the detector from rock fall. Note the umbrellas for scale.

The diversity in muon track directions needed to reconstruct 3D images can be achieved by operating several detectors simultaneously, as indicated in Figure 2, or by moving detectors sequentially to different locations and running over a longer calendar period, or any combination of the two. The setup of one UT Maya Muon detector adjacent to the base of a Maya pyramid at the La Milpa site in Belize is shown in Figure 3.

Finally, we note that muon tomography provides excellent opportunities for fruitful collaboration between diverse academic communities—physicists, archaeologists, and

anthropologists—as demonstrated by Alvarez, and taking place in a few universities today. Many physics departments have experts in particle detector systems, often with their own cosmic-ray test stands to explore new detector technologies right on campus. It is relatively simple to adapt such work to cosmic-ray muon tomography; a connection to archaeology can be a great attraction for students of both subjects to become involved. At the University of Texas at Austin, we have engaged several generations of students, with highly diverse interests, in the quest to build, deploy, and analyze data from practical detectors, based on modern technology that may teach us more about ancient societies.

The challenge today for emerging efforts in cosmic-ray muon tomography is to achieve the kind of definitive archaeological discovery that Alvarez and his colleagues produced nearly 50 years ago.

Drones

MICHAEL T. SEARCY

Brigham Young University, USA

Drones, or unmanned aerial vehicles (UAVs), are commonly used to capture data from the air, providing a bird's-eye view of excavation areas, architecture, archaeological remains, and surrounding topography. In addition to aerial imagery, various sensors are used to gather data that can be used to create different kinds of maps and images useful in archaeological investigations. Due to their size, affordability, and portability, drones are ideal for archaeological mapping, and they are quickly replacing the need for aerial photography taken from satellites, airplanes, kites, or balloons. Moreover, while satellite imagery has the advantage of providing images of large tracts of land, it is often expensive and cannot provide the resolution that a drone, flown at low altitudes, can capture. Complementary to several other mapping methods, such as traditional surveying using a total station, drones can also cover more area in less time (Gutiérrez et al. 2016).

There are many different kinds of drones, but most can be categorized as either fixed-wing or rotary formats (Gutiérrez and Searcy 2016). Most are small and lightweight, and can carry payloads that fit the needs of the archaeologist. In addition to manual flight modes using a remote control, drones can be flown by autopilot software, allowing them to fly precise transects when collecting data on specific targets on the ground. Autopilot units with programmed flight paths use global positioning system (GPS) coordinates, and this requires that the drone continuously receives locational data from GPS satellites. UAVs using autopilot software are typically controlled by handheld devices, tablets, or computers.

Drones flown with digital cameras are capable of capturing high-resolution images at varying intervals. Post-flight processing of images is necessary and usually includes software capable of "stitching" together the photos to create a

seamless mosaic of images aligned with different coordinate systems (also known as orthomosaic imagery). While some drones are equipped with receivers that record GPS data for the images they capture, others require that ground control points (GCPs) be laid across a site. GPS data are then recorded for these GCPs using traditional GPS units, and these data are used to georeference the images, creating an orthomosaic that is georectified (Verhoeven et al. 2012).

Aerial images can be used to create several other types of images and maps through a process known as photogrammetry (see PHOTOGRAMMETRY AND STEREOPHOTOGRAMMETRY), which involves taking two-dimensional, overlapping photos through a process of triangulation to develop three-dimensional (3D) images (Chiabrando et al. 2011). Aerial photogrammetry provides data that can be used for 3D modeling of sites or architecture (Verhoeven 2011). 3D models are useful for the longitudinal study of site stability and conservation or in virtual reality modeling (see VIRTUAL REALITY MODELING) for educational purposes. Photogrammetry can also be used to develop digital elevation models (DEMs) and topographic maps. Digital surface models generated from aerial photos can be used for slope surface and landscape analysis.

In order to identify archaeological features and determine their spatial distribution, researchers from several institutions used drones to map portions of Easter Island (Rapa Nui, Chile), where the famous *moai* statues were sculpted and erected by people in the thirteenth century CE (Wechsler et al. 2016). Using fixed-wing UAVs, the team was able to create orthomosaic images of several areas on the island. Using existing GPS data from previous surveys on the ground, they were able to rectify feature locations, including rectangular stone platforms (*ahu*) where the *moai* were placed, as well as their large stone hats (*pukao*) made of red scoria. They also documented cultivation features like lithic mulch gardens and other house features. Due to the precision and high resolution of the aerial images, Wechsler et al. (2016, 38) were able to take incredibly accurate measurements of *moai* recorded in

the images. Compared to measurements on the ground, those taken from the aerial imagery were within one standard deviation (Wechsler et al. 2016, 38).

Aerial thermography has the ability to detect differences between “cool” versus “warm” features, which varies depending on the amount of heat retained by different soils and/or materials (Kvamme 2008). Infrared (IR) radiation cameras are mounted to drones to record thermal data, which can be used to produce thermographic images that potentially depict shallowly buried architecture (up to 50 cm) or other archaeological features (Casana et al. 2014). Thermal images can help detect features that are near the surface, even when covered with vegetation. Thermography has been found to be especially useful in detecting archaeological features and recent excavations where loose soils retain more moisture and less heat (Casana et al. 2017). In addition, different plants can create patterns in thermographic images, which correlate with specific features. Kvamme (2008) used aerial thermography at the Double Ditch site, an ancestral Mandan earthlodge village found on the Missouri River in North Dakota. He found that several “cool” anomalies were related to “open ditches, borrow pits, and house floor boundaries,” while “warm” anomalies often indicated “packed soil beneath trails, areas of mounded earth or thick village matrix” (Kvamme 2008, 77).

Light detection and ranging (see LIDAR DATA VISUALIZATION AND PROCESSING) (LiDAR) uses laser scanning to create 3D point cloud models of the ground surface and archaeological features. The large size of most LiDAR units has required that they be carried by manned aircraft, but smaller formats are available and can be mounted to UAVs. One of the major advantages of LiDAR is the ability to filter out any interference from vegetation, providing digital terrain models that can reveal archaeological features that lie beneath a forest canopy or thick vegetation.

On their own, the cartographic outputs reviewed above provide useful data for archaeological survey or mapping, but their utility is strengthened when combined with other remote sensing methods. These include ground-penetrating radar (GPR) (see VISUALIZATION OF GROUND-PENETRATING RADAR DATA), magnetic gradiometry (see MAGNETIC FIELD

GRADIENT), or electrical resistivity (see ELECTRICAL RESISTIVITY). Drones can also be used to take digital video of site excavations that are used for promotional or educational materials disseminated for the purpose of public outreach.

While there are several advantages to the use of drones, there are some caveats. Most small-format drones require batteries that are quickly depleted after short flight times and require recharging. The compact size of UAVs also makes them more susceptible to damage or crashes during adverse weather conditions like rain or high winds. There are unforeseen technical difficulties that can result in fly-aways, crashes, or erratic movements, common also to other pieces of electronic equipment used in typical archaeological field conditions. Finally, there are restrictions in some countries regarding where and how drones are flown.

The United States, in particular, has adopted rather strict rules regarding drones used in national airspace. For those flying UAVs for commercial or research purposes, these rules include flights no higher than 400 ft (122 m) above ground surface, maintaining line-of-sight during flight, restricting operation of drones to daylight hours, and flying only drones that weigh 55 lbs (25 kg) or less. The United States also requires that commercial drone pilots be certified by the Federal Aviation Administration, which includes passing an aeronautical knowledge test and registering and marking any UAVs used for business or research (Searcy 2016).

While the use of drones in archaeology is being widely adopted throughout the world, safety protocols and standardized methods have yet to be developed. Despite this fact, archaeologists using drones continue to find new applications as smaller sensors and more powerful photogrammetric software become available.

Electrical Resistivity

ALEXIS MOJICA ABREGO

Universidad Tecnológica de Panamá, Panamá; Sistema Nacional de Investigación—SENACYT, Panamá

Introduction

Until midway through the last century, the process of excavating the anthropic and natural stratigraphies sedimented at a certain site or excavation was the only approach that an archaeologist could use to detect buried archaeological features. During this same period, the electrical method was applied for the first time as a method of geophysical surveying to assess the archaeological potential of a given site. Although the basic concepts of this method were originally established by C. Schlumberger in field tests conducted in France in 1912, its use in the field of archaeology (see FIELD SURVEY) dates from the 1940s. The electrical method was initially developed for use in mining and to search for oil, but some years later it also began to increase in importance for the assessment of archaeological sites and for finding groundwater. The technological advances of the 1980s led to the development of geophysical devices that could quickly collect and store a large amount of data, as well as computational codes that could interpret the results more accurately. Currently, electrical prospecting devices can make continuous records via mobile systems, which in conjunction with GPS technology and statistical programs can generate very high-definition maps of the spatial distribution of the electrical properties of the soil. These advances have also been extended to other types of prospecting, which we will consider later. There is extensive literature on the potential of electrical methods for resolving archaeological problems, for example, Scollar et al. (1990), Clark

(2003), Campana and Piro (2008), and Schmidt (2013).

The concept of electrical resistivity

In general, the electrical prospecting method forms part of a series of electrical methods that use a source of artificial energy, and whose purpose is to detect surface effects generated by a flow of electrical current in the subsoil (Telford, Geldart, and Sheriff 1991). These effects are used to measure the apparent electrical resistivity of the subsoil, which is the basic physical parameter for electrical prospecting and other methods, measuring how difficult it is for a certain volume of soil to oppose the passage of moving electrical charges. What we mean by moving charges in the subsoil is electronic (ohmic) conduction, which is a normal mechanism that occurs in materials that contain free electrons. However, the propagation of charges may also be electrolytic or dielectric. Thus, the measured electrical resistivity depends on pressure and temperature, as well as on chemical phenomena in the medium in which the charges are moving (Nover 2005). Certain soil properties, such as its salinity, texture, humidity, organic carbon, pH, density, nitrate content, and type, are found to be closely associated with this physical parameter. Some very common cultural features, including streets, walls, floors, dumps, tombs, caves, and trenches, have different electrical resistivity values from the medium around them.

The apparent electrical resistivity value (ρ_a) is obtained using four metallic electrodes, or a quadrupole, inserted a few centimeters into the ground. The injection of a certain density of electrical current (i) into homogeneous soil via a pair of electrodes (C_1 and C_2 in Figure 1a) using an external power source generates a potential difference (ΔV) in the surrounding area that can be registered by the other pair of electrodes (P_1 and P_2 in Figure 1a).

Each apparent electrical resistivity value is obtained using the equation:

$$\rho_a = k \frac{\Delta V}{i}$$

and corresponds to a bulk value of a continuous volume of the subsoil beneath the quadrupole. Parameter k corresponds to a geometric factor associated with the position of the four electrodes, with the measurement unit of ρ_a thus being ohm.m, which is abbreviated as .m. At present, there is a range of electrode configurations or arrays adapted to certain research goals. The most widely used arrays in archaeology are dipole-dipole, Wenner, and pole-pole (see Figure 1b).

The layout of the equipotential and electrical current lines in Figure 1a is not representative of a real medium, as the current lines would refract in the interface between mediums; and as soil is a non-homogeneous medium, what we are measuring is not real electrical resistivity but rather an average known as the apparent electrical resistivity.

Electrical mapping and electrical resistivity tomography

In electrical prospecting, there are three modes of investigation, two of which are particularly widely used in archaeology: electrical mapping and electrical resistivity tomography. The third is electrical sounding, which is less common in archaeology but can be used to obtain important information about the vertical succession of the terrain (Dabas 1999). Electrical mapping consists of walking with a device over a series of parallel profiles spaced a short distance apart from each other and recording apparent electrical resistivity values at regular intervals. This methodology can be used to define a square or rectangle over the surface of interest with perpendicular x and y axes, each recording being associated with a metric coordinate (x, y) . Figure 2a shows the acquisition chart using a Wenner array.

This dataset (x, y, ρ_a) is then interpolated using statistical programs to generate a map of the spatial variations in apparent electrical resistivity at a fixed depth (which depends on the space

Figure 1 (a) Flow of electrical current and equipotential lines (of equal electrical potential) due to two point sources of electrical current C_1 and C_2 on the surface of a homogeneous site. (b) Most commonly used electrode arrays in archaeology.

Figure 2 (a) Acquisition chart of apparent electrical resistivity values for electrical mapping using a mobile system with a Wenner array. (b) Map of apparent electrical resistivity, using Surfer 12 (of Golden Software) statistical program. (c) Acquisition chart of apparent electrical resistivity values along a profile using a resistivimeter, a multicable system connected to the electrodes, and a Wenner array. (d) Example of 2D electrical resistivity tomography obtained at a Hispanic archaeological site with a Wenner array.

between mobile electrodes) using logarithmic contour lines to make them easier to interpret. The presence of archaeological structures is revealed through the geometry of the electrical variations or anomalies that appear on the map. As an example of this methodology, Figure 2b shows a map of the logarithmic contours of the

apparent electrical resistivity at an archaeological site resulting from a dataset obtained using a Wenner array with a 1-m spacing between electrodes and 1 m between the six 20-m-long profiles. This map shows a strong linear anomaly of approximately 15 m length which was found to be associated with a buried Hispanic wall.

Due to the limited depth of electrical mapping, 2D electrical resistivity tomography is used, because it offers lateral and depth information. Figure 2c shows an apparent electrical resistivity data acquisition chart along a profile using a Wenner array. The multicable system connected to electrodes spaced at an equal distance (a) can provide considerably dense field data corresponding to multiple quadrupole combinations. Each of the apparent resistivity values obtained depends on a central quadrupole position (or the positions of each of the four electrodes) and on an

acquisition level n or electrode spacing, as shown in Figure 2c.

This dataset is subjected to a complex inversion process whereby a model of the subsoil is built through the definition of a series of rectangular prisms, for which the electrical resistivity values are calculated. This process is iteratively repeated until the difference between the measured and calculated electrical resistivity values is minimized. The result of this operation is a cross-section of the terrain that shows the real distribution of electrical resistivity in the

Figure 3 (a) Acquisition chart of apparent electrical resistivity values along several parallel profiles, and (b) example of 3D electrical resistivity tomography obtained at a Hispanic archaeological site.

subsoil at a given depth. Any electrical anomalies that appear are hence associated with the heterogeneities contained in the subsoil. Figure 2d shows the result of 2D electrical tomography obtained from processing a 360-item dataset using the Res2Dinv program (by Geotomo Software) over a 23.5-m profile with a Wenner array and an electrode spacing of 0.5 m. The lateral and depth extensions of two high electrical resistivity anomalies (>70 .m) can be seen, which are associated with the stone walls and foundations of a Hispanic site. At a greater depth, no anomalies associated with buried archaeological features can be distinguished.

Meanwhile, if we wish to obtain three-dimensional information, all we need to do is repeat the previous process over a certain number of parallel profiles. Figure 3a shows the data acquisition chart, and a detailed block of electrical anomalies, as a result of an inversion procedure using the EarthImager 3D program (of AGI Advanced) and Voxler 2 (of Golden Software) for a 3D representation, as shown in Figure 3b. The result is a three-dimensional representation using cross-sections and iso-surfaces for a set of electrical anomalies associated with the buried walls and stone foundations of a Hispanic convent.

Finally, the study of the electrical resistivity of the subsoil constitutes a powerful tool for non-invasive investigations of archaeological features buried at shallow depths. The contrast between the electrical resistivity values of these characteristics and the surrounding medium obtained in the high-resolution results provides an efficient alternative for the rapid evaluation of an archaeological site.

Electromagnetic Conductivity

EILEEN G. ERNENWEIN

East Tennessee State University, USA

Electromagnetic (EM) conductivity is a geophysical method capable of mapping conductive archaeological features such as fortification ditches, moats, middens, and other features that retain moisture and therefore have higher conductivity than surrounding materials. It is also useful for providing geoarchaeological context to sites and landscapes, such as the locations of subsurface paleochannel deposits (Conyers et al. 2008). The property electrical conductivity (EC) is a measure of how well a material conducts electricity, and is the reciprocal of electrical resistivity (see ELECTRICAL RESISTIVITY) (ER), a property typically measured by injecting electrical currents into the ground by probe insertion. EM conductivity is measured by noncontacting electromagnetic induction (EMI), resulting in a weighted average of conductivity. As such, ER and EM conductivity are not directly reciprocal. Resistive targets such as rock walls are best detected by ER, while conductive targets such as fortification ditches are readily detected by EM conductivity. Archaeological features with relatively high amounts of organic material or finer-grained sediments such as silt and clay typically retain moisture and therefore have higher EM conductivity. Principal advantages of EMI are that it does not require contact with the soil and it simultaneously measures EM conductivity and magnetic susceptibility (see MAGNETIC SUSCEPTIBILITY) (MS), a property directly associated with human activity on the landscape.

History of electromagnetic conductivity in archaeology

All geophysical methods used in archaeology have their origins in geology or related disciplines, and

EMI is no exception. In general, archaeologists must adapt instruments and field methods for archaeological use, since geologists are typically looking for larger, more robust features. By the early 1960s, ER and magnetometry (see MAGNETOMETRY) had been successfully adapted and were part of standard practice in European archaeology. At this time, mathematical models showed that EM conductivity could be measured using magnetic dipoles much like those used in a metal detector (Scollar 1962, 152), but an early prototype instrument was found to respond primarily to magnetic properties (Tite and Mullins 1969). These difficulties were ultimately overcome in the 1970s, when Tite and Mullins (1970) determined that conductivity and MS responses can be separated by using specific frequencies and transmitter–receiver coil spacing. The first commercially available instrument, the EM31 Ground Conductivity Meter, was released by Geonics Limited (Ontario, Canada) in 1976.

Theory of operation

EM fields sent into the earth will behave in one of two ways depending on their frequency. High-frequency waves (10 MHz to 2.6 GHz) will propagate through the ground and produce reflections off buried interfaces. This is the basis of ground-penetrating radar (see GROUND-PENETRATING RADAR) (GPR), a method widely used in archaeology. At low frequencies (1–300 kHz), however, EM fields will diffuse through the earth, and in this process they are modified slightly, compared to those that travel through the air. EMI instruments measure how these induced fields change in response to the electrical and magnetic properties of the ground. The source EM field is generated by running an alternating current through a coil or loop, producing fields with wavelengths greater than 1,000 m. Figure 1 illustrates how this typically occurs. The primary EM field is generated from a transmitter and travels both above and below ground. Localized electrical currents called eddy currents are produced whenever the primary

DOI: 10.1002/9781119188230.saseas0207

Figure 1 Generalized diagram of EM induction. A primary field is created by the transmitter (T) and extends outward in all directions. Conductive objects respond to the primary field by producing eddy currents, which in turn produce a secondary field. A receiver (R) measure the primary and secondary fields.

field encounters conductive features or layers. The eddy currents in turn generate a secondary EM field, and the receiver measures both the primary and secondary fields. The ratio of the secondary to the primary field is proportional to the EM conductivity of the ground.

The Slingram method

A variety of EMI systems are used in geology and other disciplines, but it is the Slingram method that is the most suitable for mapping archaeological and related landscape features. Slingram systems have transmitter and receiver coils, connected by a reference cable, typically mounted at a fixed distance on a boom, which is carried by a surveyor or towed on a sled. One of the most widely used in archaeology is the Geonics EM38 series (including the original EM38 and

the EM38DD, EM38B, and EM38-MK2 models), pictured in Figure 1. These instruments measure EM conductivity and MS at 1-m coil spacing, with the addition of a second receiver coil at 0.5 m on the MK2 model. This method of measurement is only possible when the ratio of the intercoil spacing divided by the skin depth (explained below) is much less than one, a condition known as “low induction numbers” (LIN) (McNeill 1980). Slingram EMI instruments are designed with this in mind, ensuring that frequency and distance between transmitter and receiver coils satisfy the LIN condition.

Depth and resolution

Slingram instruments can be configured in a variety of ways to target specific depths and optimize sensitivity to archaeological features. Depth is

dictated by coil separation and orientation. Most instruments have coils arranged parallel to each other, allowing them to be positioned horizontally or vertically during survey. Horizontal coils produce a vertical magnetic dipole, and vertical coils produce a horizontal magnetic dipole, with the former having a depth of investigation approximately twice that of the latter (McNeill 1980). An alternative coil arrangement places the receiver coil perpendicular to the transmitter. This arrangement improves sensitivity, but produces irregular anomalies that are not centered over their source, adding complexity to interpretation (Tabbagh 1986).

Maximum depth of investigation for EMI is known as skin depth, which is the depth at which response has decreased to 37 percent. Skin depth is irrelevant for Slingram instruments operating at LIN, however, because the depth sensitivity is controlled by weakening of the transmitted EM field as distance from the transmitter increases. Given that the transmitted EM field is elongated on the vertical dipole axis, depth sensitivity depends on the coil orientation. Figure 2 shows the relative response for vertical and horizontal magnetic dipoles as a function of depth. The horizontal magnetic dipole orientation is most sensitive to material near the sensor and the sensitivity decreases exponentially with distance away from it. Depth sensitivity for vertical magnetic dipoles is very limited at the surface, increases sharply to a peak sensitivity at a depth equal

to 40 percent of the intercoil spacing, and then falls off gradually. Thus, the vertical magnetic dipole orientations are quite insensitive to materials immediately beneath the sensor, but have a “sweet spot” of peak sensitivity not far below.

Given that the depth of investigation can be altered by coil configuration, spacing, and orientation, and that the instrument can be positioned at multiple heights above the ground surface, it follows that a single instrument can measure EM conductivity and MS at multiple depths. Several EMI instruments are configured with multiple transmitter–receiver pairs at varying coil configurations to allow up to four depths in a single pass (for example, the DualEM-21S, manufactured by Dualem, Ontario, Canada). Such multireceiver instruments are becoming the norm. It should be noted that there are also several multifrequency instruments that have been on the market for decades, which are designed to target multiple depths with a single, fixed-distance transmitter–receiver pair by broadcasting multiple frequencies. The theory behind EMI at LIN attests, however, that this is not possible at the range of frequencies and depths targeted for archaeology (McNeill 1996). Field tests show that changing the frequency of a fixed-coil instrument does not provide new information (Bonsall et al. 2013). These instruments can still collect useful data provided that an appropriate frequency is set based on the coil spacing, following McNeill’s (1980) LIN principles.

Optimal use of electromagnetic conductivity

A principal disadvantage of EM conductivity when compared to ER is that it is less able to resolve highly resistive features, such as rock walls. This makes it a poor substitute for ER in many cases. EM conductivity data closely resemble ER when target features are conductive (Kvamme, Johnson, and Haley 2006, 253), and has a proven track record for mapping fortification ditch and moat features. Given that resistivity survey is slower and often impossible when contact resistance prevents its use, EM conductivity is a logical, though sometimes less ideal, choice. In addition, it makes sense to compare EM conductivity to GPR, since both methods respond principally to electrical properties. Like ER, GPR can more reliably resolve small features. Yet, EMI survey is often faster and less expensive, and may achieve a greater depth of investigation in conductive environments. In addition, interpretation of EM conductivity data is much less complex than GPR.

EMI survey has several advantages that make it an ideal choice in certain situations. First, EMI instruments measure not only EM conductivity but also MS, a statistically independent dataset that is often very useful for archaeology. Survey is fast compared to ER and GPR, and can simultaneously measure multiple depths. Finally, EM conductivity has been shown to be of particular utility in geoarchaeology, as it can simultaneously give detailed information about geological context such as paleochannels (Conyers et al. 2008) as well as large conductive features such as moats, fortification ditches, and middens.

At present, archaeogeophysics is experiencing a rapid increase in survey speed owing to the development of multisensor carts integrated with real-time global navigation satellite systems (GNSS). GPR array systems are now being used to map large areas with great speed and precision. This approach is growing in popularity, but is still cost-prohibitive for many. Magnetometer carts having four or more sensors are more affordable and now routinely used for reconnaissance. Smaller areas are then chosen based on these results for survey with slower, more traditional single-sensors such as GPR, EMI, and ER. The

use of EMI carts for landscape-scale survey is just now emerging as an alternative or complementary reconnaissance strategy. This approach offers the ability to map geological context from EM conductivity, and locations of intensified human activity from MS.

Ethnography and Qualitative Methods in the Field

CLAIRE NOVOTNY

Kenyon College, USA

MAIA DEDRICK

University of North Carolina at Chapel Hill, USA

Introduction

Archaeologists have used qualitative methods, and ethnography in particular, to enrich their understanding of past societies and human behavior since the advent of the discipline. Early efforts in American anthropology included ethnology and the collection of Native American artifacts under the assumption that Indigenous peoples were on the verge of being eradicated. In order to understand human cultural variation Franz Boas drew on cross-cultural comparisons and promoted a four-field approach to studying culture. His work on museum collections and material culture put sociocultural anthropology and anthropological archaeology into conversation with each other. By the mid-twentieth century, the formalization of anthropology as an academic discipline led to greater separation between the subdisciplines in order to establish methodological identities. For archaeologists, this meant a decreasing emphasis on qualitative methods to understand past societies.

One archaeological approach that continued to depend on qualitative data, however, was ethnoarchaeology—the study of contemporary material culture to construct models explaining archaeological patterns. In the 1970s Lewis Binford (1978) conducted ethnoarchaeology with the Nunamiut people in Alaska. Binford was interested in observing hunter-gatherer lifeways in periglacial environments in order to form hypotheses about material patterning observed at Mousterian archaeological sites. Among other

insights, Binford documented the seasonality of hunting and resource procurement, providing a model for archaeologists to test.

While ethnoarchaeology valued Indigenous knowledge systems about culture and the environment—in contrast to earlier arguments that deemed Native Americans incapable of the technological achievement clearly displayed in ancestral architecture and artifacts—many Native peoples found the ethnographic gaze exploitative. Archaeological and ethnographic studies were conducted without the consultation or participation from tribes, and the resulting information was limited to academic circles. Native Americans found themselves distanced from knowledge of their own ancestral past.

During the 1980s, archaeologists advocating a postprocessual perspective critiqued the positivist idea that archaeological knowledge could be purely objective and instead argued that interpretations were subjective and influenced by the positionality of the researcher (Hodder 1982). Postprocessual archaeologists called for an increased awareness of how interpretations about the past can be used to shape contemporary political agendas, nation building, Indigenous land claims, and heritage rights. In some instances they also used ethnographic research or invited ethnographers to study the politics and practices of specific archaeological projects. Marxist-inspired social archaeology emphasized the study of human diversity, focusing on minorities, women, children, the poor, the enslaved, and the disabled in the interpretation of archaeological evidence. In addition, social archaeologists argued for the importance of multivocality, which considers that there are different ways of knowing the past, and these ways can be interwoven through the coproduction of knowledge to create deeper understandings of archaeological evidence. These convictions inspired a turn towards qualitative methodologies.

In this entry a suite of qualitative methods are presented that archaeologists can use in their own field projects. Each project and sociocultural context is unique, and the qualitative tools outlined in

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

this piece should stimulate discussion and creativity when it comes to understanding the past and making it relevant for the present.

Participant observation and interviews

Research participant interviews may be the most common qualitative method. The type of interview strategy chosen will depend on the research questions asked.

Structured and semi-structured interviews

Structured and semi-structured interviews are useful, as research participants are asked consistent sets of questions for the purposes of comparison. Structured interviews abide by a list of predetermined questions, while semi-structured interviews use an interview guide to maintain focus on key questions that address project themes.

Surveys or questionnaires

Questionnaires that address attitudes or opinions about history and heritage can also be used to collect high volumes of data efficiently. In Tahcabo, Yucatán, archaeologists working with the *Proyecto Arqueológico Colaborativo del Oriente de Yucatán* (PACOY) circulated a short survey questionnaire to households in different parts of the village to gauge interest in local heritage places, understand knowledge and use of the Yucatec Maya language, and identify the items and information people would like to see in a community heritage museum. The surveys helped researchers plan engagement activities with local students and design displays for the museum. Analysis of structured interviews and questionnaires can be both quantitative and qualitative.

Participant observation

For archaeologists interested in community archaeology or participatory research, participant observation is a crucial method for building rapport. For example, when first author Claire Novotny was starting a community archaeology

project in southern Belize, she went to a village and spent a month rotating between different family homes. Her participation in daily life—helping to cook meals, bathing in the river, attending soccer matches—demonstrated her intentions to work collaboratively with the village. She also met extensively with village leaders and had informal conversations with people about archaeology and heritage. That trip, while short by ethnographic standards, laid the foundation for a productive collaboration. Field notes and typed reflections provide important records of the research.

Oral histories and unstructured interviewing

During unstructured interviews, participants answer questions at their own pace and interviewers are flexible in the questions they ask, with space for the conversation to develop in unanticipated directions. In the case of oral histories, interviews are meant to elicit individuals to tell in-depth stories about their lives and the experiences of close family members. Unstructured interviews are useful during long-term field projects and are analyzed in qualitative ways.

Focus groups and community meetings

A focus group is a recruited group gathered for a structured discussion. Focus groups are convened by a moderator, who uses carefully chosen questions to guide the discussion. The goal of the session is to generate as many ideas or opinions as possible in a flexible group discussion setting. In the early stages of research, a charrette, which is a type of focus group, can be a useful method for joint decision-making. A charrette is a collaborative planning process that teams academics with local experts to accelerate research and ensure it is designed and disseminated appropriately (Roggema 2014). Another technique that uses focus groups is Photovoice (see below).

The community meeting is an important component of communicating with the public. Group meetings can be used to gauge community values and interest in archaeology, plan research designs, elicit research questions about the past, give feedback about research, or brainstorm for future

activities or projects. There are many guides online about how to conduct focus groups, charrettes, and community meetings. Community organizers and grassroots development groups have produced useful information that can assist archaeologists.

Participatory research

Participatory research is conducted in partnership with communities: it is conducted *with* rather than *on* research participants. Participatory research can encompass one element of a project or constitute the design of the project in its entirety. Community partners participate in all phases of a truly collaborative project, from design through interpretation and publication. Scholars conducting research in a participatory way strive to democratize knowledge production by working with communities to identify local needs relevant to research questions as well as opportunities for meaningful action and dialogue. All the qualitative methods described above could be used to conduct participatory research, but group methods such as focus groups may be the most appropriate for incorporating a wide range of local perspectives and taking into account the power structures at play (Pollack 2003).

Participatory archaeological research empowers communities to reclaim their histories, while providing opportunities to understand them better. The Market Street Chinatown Archaeological Project is one example of collaborative research developed as a partnership among academics, cultural resource experts, and the Chinese descendant community. In this case, the local Chinese American population helped to develop new research questions (Voss 2005: 434) as well as exhibits and educational programs. Atalay (2012) has written about archaeological projects that adhered to the standards of community-based participatory research (CBPR), a term that originated in the field of public health. All five projects discussed in her book brought reciprocal benefits to the partners involved and acknowledged the value of bringing together diverse knowledge systems.

One strength of implementing CBPR is the coproduction of knowledge; research questions

and agendas are generated by local communities in partnership with researchers. Democratizing the process of knowledge production addresses power imbalances in archaeology (and the social sciences more broadly) in which researchers control and restrict access to data, interpretation, and results. When communities take part in setting priorities and guiding the research process, the resulting knowledge can be controlled by and serve the needs of community members. Additionally, participants can contribute their expert knowledge about their communities to the research, providing a more holistic rendering of history. The democratization of knowledge production about the past empowers communities to make decisions about their heritage, while also strengthening research outcomes.

Record keeping and transcriptions

The seemingly simple act of taking notes frames archaeological interpretations and ethnographic interactions and can privilege some voices and ways of knowing over others. Recent scholarship has highlighted the ways in which new technologies allow for more systematic categorization and recording of the qualities rather than just quantities of archaeological data. These include opportunities for archaeologists in the field to make more culturally relevant observations of the matrix textures and artifacts that they encounter (Jackson, Motz, and Brown 2016).

Ethnographic note-taking, audio recording, and transcription

Ethnographic research depends on accurate note-taking. Some notes occur in the field as memory devices, while more thorough note-taking occurs later. Besides description, notes should include reflection, new questions, and emerging themes. Audio or video recording will also prove critical for future observations about the nuances of an interview or focus group. Transcription is an important part of the analysis process—typing up the script of what was said provides an opportunity to hear the information in new ways. Software exists to facilitate transcription; for example, one can change the audio

file speed, add timestamps, and access shortcut keys that simplify the process (e.g., f4transkript; Express Scribe). Next, some researchers apply codes to transcripts either freehand or using analysis software (e.g., Atlas.ti). This can help researchers to track themes that came up during the research and even model the connections between data points.

Institutional Review Boards (IRB) and consent

The Institutional Review Board (IRB) process was designed for the health research sector, but can prove useful to archaeologists engaged in ethnographic research as a technique to think through possible research risks and benefits. All of the above-mentioned methods, due to the participation of human subjects, must be approved or deemed exempt from the process of review by the principal investigator's IRB, based at their university. While funding agencies often require receipt of IRB approval or exemption, it is the responsibility of the researcher to pursue the review process, whether or not it is common practice in the host country. In accordance with IRB standards of ethics as well as those of professional organizations, consent must be obtained from any research participants or informants. The IRB offices at some universities have pioneered alternative ethics trainings for individuals who do not have easy access to computers or who do not read at a high level of proficiency, which can be important for projects in which local residents participate in the analysis of ethnographic data. All research team members should be trained in human research ethics.

Social media and mixed media

Public archaeology projects often use technology and social media to share knowledge with interested parties. Blogs have been a common tool used to share the processes and discoveries of archaeological excavation, laboratory analysis, and interpretation. In some cases, the goal is to expand the geographical spread of archaeological information and teaching resources, while in other cases, online tools allow for deeper local

engagement with the archaeological project. Online publications are broadening the audience for digital media related to anthropology and archaeology through high standards of journalism and the availability of multiple transmission formats including photo essays, which are commonly too expensive for print media (e.g., SAPI-ENS, www.sapiens.org). Digital servers also offer platforms to share data among scholars, including open-access archives, articles, and journals.

Other valuable examples of mixed media efforts include performance ethnography, participatory filmmaking, and Photovoice. Photovoice is a problem-based technique that uses photographs taken by community members as the basis for discussion and action related to local needs. The main goals of Photovoice as described by Wang and Burris (1997) are: (1) to identify community strengths and challenges, (2) to promote dialogue of important issues through discussion of photographs, and (3) to create change. This method can be an efficient mechanism to assess community values and to consider ways in which an archaeological project can contribute to the place where it is based. The process of Photovoice involves several meetings with a small group of participants, each of whom receives a disposable or digital camera. During the first meeting, facilitators describe the project, obtain consent, and receive training in photographic skills, and the group as a whole decides on the question to be considered through photography in the coming week. In subsequent sessions, in-depth discussion of photos takes place, leading to an analysis of the problem and the development of action steps. Transcripts of the discussions are distributed to participants and studied collaboratively. For an example of an archaeological application of Photovoice, see Dedrick (2018).

Ethnohistory

Ethnohistory is grounded in the collection and analysis of ethnographic and historical data, and has proved incredibly useful in historical archaeology. It extends the analysis of historical documents to include materials such as maps, folklore and oral histories, traditional knowledge, archaeological artifacts, museum collections,

and artwork. The goal of ethnohistory is to understand the history of a cultural group on its own terms; this is especially useful for Indigenous peoples, whose histories have been recorded and distilled through a Western lens.

An excellent example of ethnohistory is the San Pedro Valley Ethnohistory Project in southern Arizona. The project blended ethnographic, historical, and archaeological information to gain a deeper understanding of how Native Americans have related to the San Pedro River Valley over time. From 2001–03, team members collaborated with the Hopi, Zuni, Tohono O'odham, and San Carlos and White Mountain Apache tribes to investigate themes of social identity, migration, warfare, subsistence ecology, and population density in the San Pedro Valley (Ferguson and Colwell-Chanthaphonh 2006: 6). Fieldwork included archaeological site visits, museum research, and interviews. Conversations and reflections from the field were starting points for later semi-structured interviews with participants (Ferguson and Colwell-Chanthaphonh 2006: 19). Taking into account how material culture, language, and oral traditions interweave to form historical narratives contributes a humanistic view of the past and reaches towards equitable conservation and management of heritage resources.

Future directions

Qualitative methodologies provide avenues for collaboration with stakeholders as well as ways to gauge the salience of research projects for the public. Employing qualitative methods in archaeological contexts spurs innovation and creativity. For example, the field of digital humanities is emerging as an endeavor through which archaeologists can visualize and present material culture and qualitative data (Berry 2012). Digitization of archaeological and heritage-related materials, including texts, images, and audio-visual materials, mediate the ways in which researchers and stakeholders can analyze and consume archaeological knowledge.

Field Survey

EDWARD B. BANNING

University of Toronto, Canada

As many kinds of archaeological research demand information at the scale of regions or landscapes rather than individual sites, field survey has been integral to archaeology since the pioneering antiquarian reconnaissances of the nineteenth century. It has developed into a suite of methods that help archaeologists to sample the archaeological resources of a region, to maximize the probability of discovering a particular site or kind of site, to understand ancient landscapes, settlement and land-use systems, and communication networks, and to minimize the probability that development projects will damage significant archaeological resources (see ASSESSMENT: HERITAGE IMPACT (HIA)). Each archaeological objective and field context calls for a different approach to survey design. Whether the objective of the survey is simply to find sites, to learn about the spatial distribution of sites or artifacts, or to estimate the parameters of some population of sites or artifacts, what this object is should have a particularly important impact on the survey strategy.

Broadly speaking, surveys fall into two major classes (Banning 2002). Surveys whose main purpose is to search for a particular “target” or class of targets constitute prospection; surveys meant to yield a representative sample of a landscape or the archaeological resources in that landscape may be called sample surveys (see SAMPLING THEORY). In addition, we may further distinguish surveys on the basis of the way in which the survey effort is distributed and the methods used to detect archaeological remains.

A targeted or purposive survey invests survey effort intensively in the spaces most likely to contain the archaeological evidence of interest, typically by using a predictive model in a geographic information system (GIS; see PREDICTIVE MODELING) with reference to geoarchaeological evidence, and consequently is

prominent in prospection. Sampling surveys typically begin by formally subdividing the region of interest into either geometric (typically square) or more natural or convenient spatial units and then sampling these units either randomly or systematically, or surveying all the spatial units evenly, through what archaeologists often call a “full-coverage survey.” However, that term is somewhat misleading in its implication that it results in a full inventory of archaeological remains, as the extent to which full-coverage surveys represent all the sites accurately depends on intensity or amount of effort devoted per unit of space.

Surveys also vary in their methods of detection. The most common types of survey involve fieldwalking: teams of archaeologists walk through fields, preferably after plowing and disking, or through pasturelands, preferably when vegetation is sparse, and examine the ground in their path, searching for artifacts that are visible on the modern surface to their unaided eyes. Because archaeological remains are often buried or their surface visibility is poor, however, this method is only very effective when sites are shallow and the topsoil is thin, plowed, or disturbed. In areas of poor visibility, such as forests, or where artifacts are likely to be deep, as in alluvial or colluvial contexts, it is often necessary to use either intrusive methods, for example, shovel testing, trenching, coring, and augering, or remote sensing, for example the ground-penetrating radar (GPR), the magnetic or electromagnetic survey, or aerial reconnaissance for “crop marks”—that is, the traces of buried walls and ditches that are visible in the color and height variations of plant cover. However, most of the alternatives to fieldwalking are more costly and their probability of discovering sites or artifacts of interest depends greatly on the spacing of observations and on the degree of contrast between archaeological features or artifacts and the sediments in which they occur.

This brings us to the suite of factors that affect survey results, and especially the probability that a detector (including human eyes) will successfully detect and recognize an archaeological

target. One of these factors, already mentioned, is visibility, which is the degree to which the target “stands out” from its surroundings and depends a great deal on such things as vegetation cover, presence of natural stones that could be confused with artifacts, soil moisture (in the case of crop marks and resistivity survey), and even weather and light conditions. Another factor, often called obtrusiveness, has to do with the characteristics of the target itself, such as the size of a site and whether or not it has a mound or architecture, the magnetic susceptibility of a feature, or the color and reflectivity of a potsherd (Schiffer, Sullivan, and Klinger 1978). However, these characteristics still need to be evaluated in the context of visibility, as a brightly colored sherd, for example, is easier to detect visually on a bland background of contrasting color than on a diversely or similarly colored background. Another important factor is intensity, or the density of the search effort; obviously, devoting more time to searching a given space, or spacing shovel tests or fieldwalking transects more closely, yields a higher probability of detecting things than would a faster or less dense search (Krakker, Shott, and Welch 1983; Plog, Plog, and Wait 1978). The geometry of search grids also has a tremendous impact on the probability of finding sites or clusters of artifacts (Plog, Plog, and Wait 1978; Verhagen and Borsboom 2009). Finally, many aspects of the detector (including the human detector) are relevant to survey results; both people and instruments vary in their abilities and are never perfect (Banning, Hawkins, and Stewart 2011; Plog et al. 1978).

Evaluating surveys and survey design

Inevitable variations in all these factors can make it difficult to compare surveys, or even to be confident, in the case of heritage management, that the survey will have discovered all the significant archeological remains that may exist in the space under survey. Consequently, we should evaluate surveys both during and after their implementation, as a quality assurance practice (Banning 2002; Banning et al. 2016). These evaluations allow us both to make more realistic use of the survey data and to design more optimal surveys.

We can evaluate those aspects of a survey that concern the effectiveness of detection with the aid of search theory (Koopman 1980; Stone 1975). One kind of function describes the relationship of search effort to the probability of discovery; another describes the way in which discovery probability declines with range away from the detector (be that an instrument or the fieldwalker’s eyes).

Whether we measure the search effort as the amount of time devoted to searching a space, as the total length of all search paths across the space, or as the total area of shovel tests or auger holes dug into the space, the search effort function is nonlinear. Specifically, the probability of discovery increases with the effort, but the slope of the relationship declines, so that the curve begins to level off. This happens for a variety of reasons, including that the number of detectable targets is finite and that continued survey will sometimes be redundant. This relationship has implications for how much survey we should devote to a space before it makes more sense to move on to some other space.

The function that describes the relationship of range to discovery probability is typically S-shaped, with fairly high probabilities of detection close to the surveyor’s path that at first decline rapidly with distance before levelling out into a long tail of values approaching a probability of 0, much like a normal distribution centered on the search path. We can estimate range functions under a variety of conditions and detectors by experiment (Banning et al. 2011; Banning et al. 2016).

Once we can estimate a range function for a particular context (combination of artifact type, visibility, and crew abilities, for example), we can use it to estimate a “sweep width” (Banning et al. 2011). Whether by fieldwalking or some other method, sweep width is double the range within which the number of artifacts we fail to discover is equal to the number of those we do discover outside that range. Consequently, it is the width within which we find as many artifacts as we would have found, had detection been perfect within, but zero outside, that width. Multiplying sweep width by the total length of paths walked within a space produces the “area swept,” and dividing the area swept by the area of the space being surveyed measures “coverage,” one of the

most useful measures of survey thoroughness. Although 100 percent coverage would be ideal, it is often far too costly; but it makes sense to know what a survey's coverage was if we are to interpret its results accurately.

We can use the information from evaluation to optimize surveys for our primary goals. For example, when it is extremely important for a survey not to miss particular kinds of artifacts (in other words, to have nearly 100 percent coverage for that type of artifact), we can use estimated sweep width to establish the spacing between surveyors that will accomplish this. Since it is not uncommon for sweep widths to be smaller than 2 m, this could result in very costly surveys, but we can also use sweep widths to balance cost with coverage, potentially deciding, for example, to compromise at 30 percent or 50 percent coverage for artifacts, acknowledging that coverage for large sites could be close to 100 percent while coverage for very small ones might be very much lower.

Technologies for field survey

To date, the most common method for archaeological survey is still fieldwalking, which has been the focus of most of the discussion above; and it is supplemented by subsurface testing through shovelling, trenching, augering, or coring (see AUGERING and CORING). However, other technologies for detecting the distribution of archaeological resources on landscapes are increasingly important.

Many of these technologies involve remote sensing, either from aircraft or from satellites. The imagery from aircraft has been important since the 1920s and still tends to have the advantages of high resolution and, in some cases at least, historical depth (see AERIAL PHOTOGRAPHY and AIRBORNE LASER SCANNING AND LIDAR). In regions where there has been considerable development recently, for example, old aerial imagery from the 1920s to the 1970s can often reveal traces of archaeological sites that have since suffered destruction, major degradation, or reductions in visibility. The gradual declassification of more recent satellite imagery means that this class of data is approaching the resolution

of the aerial photographs while also, in many cases, providing data outside the visual spectrum. Space-based radar or LiDAR has been particularly helpful to archaeologists, allowing for example the identification of Mayan structures that would be obscured by vegetation in more conventional aerial photography, as vegetation is transparent to radar.

Many ground-based remote-sensing methods for detecting buried features and artifacts have been available for more than half a century but, for practical and budgetary reasons, remain restricted in their application. Magnetometry (see MAGNETOMETRY), electrical resistivity survey, electromagnetic survey, and ground-penetrating radar can all be highly effective in some contexts for detecting buried walls, ditches, and other features, and sometimes large or highly obtrusive artifacts, but tend to require very closely spaced observations and generally work better in areas where we already know that there is a site of interest. It remains rare for these methods to be used for the discovery, rather than the evaluation and interpretation, of sites.

In some regions of the world, artifacts are rare or poorly preserved, and sites are effectively invisible to most of the methods mentioned above. This is particularly true in some tropical regions, where acidic soils have corroded away most traces of ancient activity. However, chemical traces can persist and, in these regions (and elsewhere), one strategy is to search for sites by their chemical signatures (see CHEMICAL MAPPING). Places where humans have deposited considerable amounts of organic trash can have elevated levels of nitrogen and phosphates (see SOIL PHOSPHATE CHEMISTRY and SOIL SURVEY), so analyzing soil samples taken over a grid of locations can sometimes identify settlement sites. These types of survey have recently benefitted from the availability of portable X-ray fluorescence analyzers (pXRF; see PORTABLE X-RAY FLUORESCENCE SPECTROMETRY (PXRF) and X-RAY FLUORESCENCE SPECTROMETRY (XRF)), which allow fast results while still in the field, so one does not have to wait for lab analyses after each field season.

Underwater and intertidal surveys are also special cases. While survey in intertidal zones (between high and low tides) can use many of the same methods as terrestrial fieldwalking, tides and their effects on the time available for

fieldwork and on the visibility and distribution of archaeological remains in this zone can be quite challenging. Underwater survey is especially challenging, because visibility tends to be very poor and the amount of time for which divers are able to stay down can be very limited. However, such surveys, especially when targeted through some combination of predictive modeling, boat-based sampling, and remote sensing (see SONAR AND SIDESCAN SONAR), can be extremely useful for identifying archaeological evidence of coastal occupations during periods of low sea level, such as the early Holocene, not to mention the survey for shipwrecks.

Geomorphological Survey

CHRISTOPHER L. HILL

Boise State University, USA

Because of its value for understanding the evolution of landscapes related to past human activities, as well as for interpreting environmental contexts (see ENVIRONMENT AND LANDSCAPE) and the dynamics of site formational processes (see FORMATION PROCESSES), the geomorphological survey is an essential field method in archaeology. The major dimensions and goals of a geomorphological survey are to identify and document (a) the types of landforms within a landscape, (b) the processes that have led to their formation, and (c) the long-term changes in the landscape. The geomorphologic survey is thus focused on both process and product; it is concerned with inferring the dynamics of landscape change as reflected in sediments, stratigraphic sequences, and landforms at a variety of spatial and temporal scales. The results of a geomorphic survey are essential to the successful interpretation of the archaeological record, providing the opportunity to examine and gain a clearer understanding of the natural and human (anthropic) processes that contributed to the evolution of the landscape. Because both natural processes and human activities can contribute to the formation of a landscape, an interdisciplinary approach that integrates the geomorphological survey is critically important to any archaeological field study (see FIELD SURVEY); it is part of the geoarchaeological (see GEOARCHAEOLOGY) approach to archaeological interpretation and also environmental archaeology (see ENVIRONMENTAL ARCHAEOLOGY).

The integration of the geomorphological survey in archaeological studies and investigations of human–environment interactions at the landscape-scale has evolved since the late 1800s when John Wesley Powell incorporated landscape dynamics and land-use in his research. During the early 1900s O. G. S. Crawford used aerial photography to place archaeological sites within

the context of broader landscapes in Britain. Raphael Pumpelly conducted a landscape study in Turkestan related to the origins and growth of the Anau civilizations, while William Morris Davis and Ellworth Huntington studied the geomorphic evidence for a series of glacial-interglacial episodes that documented regional Quaternary climate and environmental change in the region. During the 1920s and 1930s Elinor Wight Gardner conducted geomorphic surveys in the Western Desert of Egypt in the Fayum and Kharga Oasis. Carl Sauer developed an approach that viewed landscape as a product of space, time, and natural and human processes, and Kirk Bryan played a prominent role in applying geomorphical survey to the investigation of Quaternary landscapes in North America. In 1940s, Herbert E. Wright, Jr. conducted geomorphological studies in the Near East at Ksar Akil and Jarmo.

In the 1950s Fred Wendorf and John Miller applied a landscape approach to study the relationships between alluvial terraces and Pueblo sites in New Mexico, Sheldon Judson conducted a geomorphic study linked to Paleolithic sites in the Dordogne region of France, and Karl Butzer mapped surficial deposits related to archaeological sites in the Nile Valley. Field studies conducted by Chris Kraft, Stan Aschenbrenner, and George Rapp in the 1970s focused on the paleogeography of the coastal plain of Greece. Bruce Gladfelter (1977) advocated a geomorphic approach that emphasized the depositional context at site-specific location, local landscape (habitat), and regional scales.

The importance of the geomorphic survey in archaeology is that it is a way to develop a clearer understanding of the natural and human processes that have produced the landscape context (Butzer 1982). The landscape context can be defined at the level of a regional ecosystem consisting of the landforms and topographic setting of the area. The geomorphic survey is also concerned with the sequence of events recorded by the individual sedimentary sequences and evaluating these local physical sequences in terms of the broader regional-scale landscape history.

It involves understanding the erosional (see *EROSION*), depositional, and soil forming events that create the present-day landscape; these are the landscape-scale formation-processes associated with the destruction, transformation, and preservation of the archaeological record (see *FORMATION PROCESSES*). The geomorphological survey also is valuable in providing a temporal context, correlating sites and related deposits, predicting and explaining site location, and evaluating the potential site restructuring. In general, the geomorphological survey provides information on both the spatial and temporal contexts at multiple scales.

The primary objective of the geomorphological survey is to document the features of the present-day landscape and evaluate the processes and dynamic components that have actively transformed the landscape over time. Because the landscape can be considered a product of alternating periods of erosion, deposition, and stability, different conditions may prevail and be associated with specific, contemporaneous landforms. While the geomorphological survey is focused on landscape-scale studies, the scales of study can range from regional mapping to detailed studies of sedimentary sequences and individual deposits. Regional and site-specific scale archaeological interpretations can be strongly influenced by the dynamic processes involved in landscape evolution and the geomorphological survey should be an integral part of any archaeological field study.

At a minimum, the geomorphological survey should result in a map showing the spatial distribution of landforms and the map should be accompanied by a detailed description of the sediments that compose the landform. Thus, a key objective of a geomorphological survey is a surficial geology map, typically showing the distribution of late Cenozoic strata and sediments. A geomorphologic map of the landscape is based on the spatial extent and relationships of landforms, as well as the compositional characteristics and ages of the sedimentary deposits. These kinds of maps are typically initially developed using aerial photographs, satellite images, and existing topographic maps as a basis for extensive field studies. The maps categorize the various geomorphic units (such as alluvial fans, floodplains, terraces) and provide a means of documenting

the processes involved in their formation. To be relevant to the archaeologist, the geomorphologic information must be related to the archaeological materials found on or within the sedimentary deposits that compose the landforms.

Preliminary regional-scale methods of mapping employ satellite imagery (see *RADAR*) and aerial photographs (see *AERIAL PHOTOGRAPHY*) as well as available topographic maps and DEMs (digital elevation models). Topographic maps are also essential; they provide more than just elevational data and may need to be at customized scales. Geologic maps are useful, as are soil survey maps (see *SOIL SURVEY*).

While preliminary mapping plays an important role, the geomorphological survey is fundamentally a field-based approach. It is in the field that the ground-truth testing of the preliminary mapping is conducted and where direct observations are made and data are collected. Typically, at the preliminary stage the geomorphic surfaces are mapped using available topographic maps or aerial photographs and these interpretations are then field-checked. The field check can be based on natural exposures or deliberately excavated stratigraphic trenches, or cores. In the field, the objective of the geomorphological survey includes the observation and description of stratigraphic sequences. Besides using stratigraphic profiles available from archaeological excavations, the geomorphological survey will examine natural exposures or conduct additional coring and trenching. To collect detailed information regarding the lateral extent, depth, and composition of landforms, field techniques such as description of natural exposures or outcrops, or augering (see *AUGERING*), coring (see *CORING*), manual trenching, or excavation by machine are applied. These techniques provide important details about the deposits themselves (boundary characteristics, texture, composition, structure, presence or absence of artifacts and fossils). Field descriptions of sediments and soils provide a way to document and describe the stratigraphic sequences and these descriptions are used to infer the processes of deposition and soil formation. Once exposures have been described, samples may be collected for further physical or chronometric analysis (see *DATING CERAMICS AND LUMINESCENCE*).

While most geomorphological surveys apply a multi-scalar approach to investigating the evolution of landscapes, as an archaeological field method the geomorphological survey has as a primary objective the creation of a surficial geology map that can provide the basis for archaeological sampling and explanation. As part of this surficial geological map, the landscape is subdivided into geomorphic zones, or landforms. Morphostratigraphic units for surficial studies are identified or described based on surface form and not necessarily based on distinctive lithologies. Typically morphostratigraphic mapping will include defining surfaces that are indicative of an erosional or depositional process and are defined by both the processes of formation and the sediments. For example, a geomorphic survey along the Big Fork River in northern Minnesota used aerial photographs and topographic maps to develop a model of the surfaces and sedimentary deposits associated with Archaic and later Holocene archaeological occurrences, which were further investigated by field excavation and coring as well as detailed laboratory sedimentological analyses (Hill, Rapp, and Jing 2011). The ultimate product from this type of study is a map that documents the surface type and relative position of landforms within a landscape. One approach to integrating surface morphology with the sedimentary sequences within the landforms is by defining mappable bodies of sediment as allostratigraphic units. This type of classification requires field description recognition of the boundaries. A key objective is establishing the age relationships or sequence of landforms. The bounding discontinuities for allostratigraphic sequences can be erosional disconformities, soils, or landform surfaces.

In terms of archaeological goals and questions, the geomorphological survey is especially crucial in attempts to infer the environments and natural resources related to human presence on a landscape, predicting the location of archaeological entities, estimating the age of deposits containing artifacts, documenting the stratigraphic and landscape contexts related to the archaeological record, identifying and describing site matrix and evaluating events of site formation particularly those resulting from geologic restructuring. Thus, the geomorphic survey provides a way of not only predicting the locations of buried

preserved archaeological remains, it can also contribute to understanding what processes may have restructured the original spatial and compositional characteristics of human activity. These processes include surficial rearrangements (such as by running water), weathering, and burial (see TAPHONOMY).

Because the geomorphological survey can result in a well-defined spatial and temporal framework for the landscape under study, it is useful in archaeological site modeling and prediction, and testing. Site predictions, especially buried site prediction models, typically involve the integration of geomorphic, sedimentary, and stratigraphic information derived from a geomorphological survey. The mapping of landforms and the associated sedimentary packages provides a way to predict what locations may contain potential buried archaeological features. The geomorphic survey can help distinguish what landforms and accompanying deposits may have buried surfaces, soils, or be redeposited, as well as aid in determining whether the sequences are too old or young to contain archaeological materials.

Besides the adoption of technological innovations in GIS for mapping and chronometric studies, future applications may see further integration of the geomorphic survey as a key component of geoarchaeological and geoeological perspectives. As examples, the approaches to study human–environment interactions utilized by Colton (2009) in an archaeological and geomorphic survey in East Africa, and Schmitt et al. (2017) in the North American Great Plains rely heavily on geomorphological survey. In addition, in a partial response to attempts to understand the impact of humans on environmental systems, the geomorphological survey has the potential to play a valuable role in the study of the evolution of watersheds, with the goal of gaining a better understanding of the temporal and spatial parameters of human impacts and climate change on environmental systems.

A geomorphological survey is a key component of any archaeological or geoarchaeology field study. The main objective is to determine the landscape evolution of a region but it also includes specific studies of sediments and stratigraphic sequences. The geomorphic survey is primarily a field methodology but it also includes a pre-field planning and preparation stage and

can incorporate laboratory studies. The geomorphological survey takes a broad approach to understanding archaeological site context, examining the details of a site matrix, and placing this within the context of the landscape.

The geomorphological survey applies the study of landforms and landscape evolution using compositional, spatial, and temporal data integrating morphology, sedimentology, soils, stratigraphy, and chronology. This study of the landscape provides a broader-scale framework for correlations and sequencing (chronology) and more site-specific formation processes. When initiated before a regional archaeological survey (see FIELD SURVEY) is conducted, the geomorphic survey can produce a geomorphic model that can be used to predict the location and ages of archaeological or fossil sites as well as provide stratigraphic correlations. A geomorphological survey contributes to the objectives of understanding how the landscape has been influenced by natural and human systems, and the ways that Earth's physical processes have had an impact on the archaeological record.

FURTHER READINGS

GPS (Global Positioning System)

HENRY CHAPMAN

University of Birmingham, UK

The use of satellite-based navigation systems such as the global positioning system (GPS) has been revolutionary within archaeological fieldwork and research. Unlike more traditional methods of survey, satellite-based systems have the capability of providing absolute positions without reference to known points and without the need to maintain lines of sight across a survey area. These technologies have enabled archaeologists to determine positions on the ground, to establish control for other survey methods, and to record three-dimensional (3D) positions rapidly and accurately for a variety of different purposes. From establishing control networks, to recording the location of trenches, finds, and features, to assisting in the automation of data collection, satellite navigation systems are improving the ways in which fieldwork can be conducted. Furthermore, they are enabling archaeological projects to become more ambitious. More recently, the integration of satellite-based navigation within portable devices such as smartphones has opened up a new range of opportunities for archaeologists.

While in many contexts the term “GPS” has become synonymous with satellite-based navigation and survey, it is one of a series of systems which are collectively referred to as global navigation satellite systems (GNSS). GPS was the first to start development in the early 1970s under the direction of the US Department of Defense, becoming operational in 1995. Initially, the system’s accuracy was purposely decimated through the addition of selective availability (SA), although this was discontinued in 2000. While GPS remains the most commonly used GNSS, the development of the Russian system GLONASS (GLObalnaya NAVigazionnaya Sputnikovaya Sistema, or GLObal Orbiting Navigation

Satellite System) also provides global coverage for positioning and surveying. The development of the GLONASS system commenced within what was the Soviet Union just three years after GPS with the constellation of satellites launched by 1995, although it was not until 2011 that the full orbital constellation was restored with global coverage. A system developed by the European Space Agency called Galileo was initiated in the late 1990s with full development since 2003 with the ultimate aim of global coverage. Similarly, the Chinese BeiDou Navigation Satellite System currently provides positioning across much of Asia and the Pacific but is aimed to provide global coverage by 2020. Other regional systems are also currently in development. The Indian Regional Navigation Satellite System (IRNSS), more commonly known as NAVIC (NAVigation with Indian Constellation), has been in development since 2010, with the final satellites launched in 2016 providing coverage for India with a buffer of 1,500 km.

Satellite-based navigation systems provide positioning using the principle of trilateration. Satellites each broadcast a microwave radio signal which can be received by appropriate equipment. Essentially, the distance between the satellite and the receiver can be calculated on the basis of the time delay between transmission and receipt of the signal. Satellites also provide an almanac of their predicted positions so that, since the positions of the satellites are known, the simultaneous measurement of distance from multiple satellites means that the position of the receiver can be determined. If four or more satellites are tracked by the receiver at any one time, 3D positions can be computed (see El-Rabbany 2006). Because of the way in which GNSS positioning works, best results occur when the survey equipment is able to receive signals from a well-spaced series of satellites, providing better geometry for trilateration. Where satellites are clustered, such as when the surveyor is working in a steep-sided valley with limited view of the sky, the satellite geometry can be poor, leading to a reduction in precision, often shown on surveying equipment as a dilution

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

© 2018 John Wiley & Sons, Inc. Published 2018 by John Wiley & Sons, Inc.

DOI: 10.1002/9781119188230.saseas0268

of precision (DOP). The result of poor geometry might result in either poor precision of position or the inability to record a specific point. Other factors also have an effect on the capabilities of satellite-based navigation. The sky view (enabling the receipt of satellite signals) can be affected by physical obstacles such as buildings and vegetation, and hence these systems will not normally work inside and work poorly in dense woodland. Sometimes errors can occur due to the reflection of signals off of nearby structures, and this is known as “multipath.” Additional errors might arise from the conversion between global, spherical coordinate systems (such as World Geodetic System 1984, or WGS84) and planar national grids.

Typically, the precision of points using GNSS will be limited to perhaps 5–10 m at best, although there are various ways of improving this, such as the assisted GPS (A-GPS) offered on some smartphones. Within this context, GNSS-receiving equipment is commonly referred to in relation to three grades which broadly equate with financial cost: navigational/recreational grade, mapping grade, and survey grade. Navigational/recreational grade receivers assume no additional correction, being that suitable positioning for way-finding is already provided at this lower precision. Mapping and survey grade systems are dependent on the receipt or collection of additional data to provide corrections. Traditionally, such accuracy was provided by the use of two receivers collecting the same data simultaneously, with one of the two remaining static throughout (normally on a tripod). Such “differential” approaches meant that relative precision could be calculated to the centimeter level, although absolute positioning still required correction to local detail. Absolute precision can be obtained by accessing commercial networks of static GNSS receivers, either directly through mobile phone connections or downloaded for post-processing to provide corrections. These services commonly work on a subscription basis and can provide differing levels of accuracy from less than 1 m to a matter of centimeters in real time.

The value of GNSS to archaeology extends across a wide range of different survey activities (see DIGITAL CARTOGRAPHY). Even at the navigational/recreational level, absolute positioning can assist in revisiting or locating sites

and finds much more rapidly and effectively than was previously possible, and has particular value in areas where local detail is lacking, such as moorland. The integration of such systems with mapping technologies such as geographic information systems (GIS) has brought much traditionally desk-based work into the field. Even with GNSS-enabled smart phones, the potential to take geo-referenced photographs which can be presented within freely available mapping software demonstrates some of the huge potential even at entry level. With the centimeter accuracy available through survey grade systems, much more has been possible. The ability to establish a network of absolute points across a site can facilitate much more efficient and effective survey using other methods. For example, the establishment of such control points has reduced the need for traversing using optical survey equipment, with the reduction in the potential for errors. As such, GNSS systems are frequently used to establish control for archaeological sites rather than for the collection of survey detail which is undertaken using other methods. However, satellite systems can also be used for on-site setting out and recording. From the establishment of site grids (e.g., for field-walking, geophysics, or excavation) to the recording of trench edges, grid pins, small finds, and levels, such systems can provide rapid collection of data by a single surveyor. Similar approaches are also possible using equipment such as robotic total stations (see TOTAL STATION), although without the capability of absolute positioning.

Given the speed of 3D data collection using satellite-based surveying equipment, such systems have opened up the capability for undertaking topographic surveys rapidly and effectively that can be processed to generate 3D surfaces. Such methods can be used to undertake rapid earthwork surveys, although there has been some debate about the value of such methods in relation to the subjectivity of traditional earthwork survey (e.g., Bowden and McOmish 2011). Despite these debates, the generation of surface models in software such as GIS provides the possibility of performing surface analyses and for the identification of ephemeral features that might not be recognized using traditional methods (e.g., Chapman and Van de Noort 2001). It also provides the capacity to integrate

topographies with other collected or modeled 3D data. Similar capability is now provided by technologies such as laser scanning (see LASER SCANNING) and photogrammetry (see DIGITAL PHOTOGRAMMETRY).

Perhaps one of the most exciting areas of development that has been facilitated through the use of satellite-based navigation systems lies in the way that receivers can be mounted with other sensors. In the case of geophysics, this has been revolutionary. Whereas traditional geophysical surveys normally required a grid to be established within which data were collected systematically, the ability to link GNSS positioning with geophysical data collection has meant that data can be collected directly without the need for any pre-established grid. Where the data are integrated and shown on screen to the surveyor in real time, surveys can be undertaken to avoid any gaps. Such systems have been effectively used in relation to pedestrian survey and also mounted on vehicles to undertake rapid data collection across entire landscapes (e.g., Gaffney et al. 2012).

The benefits of satellite-based surveying have opened up other avenues for archaeologists. Light detection and ranging (see AIRBORNE LASER SCANNING AND LIDAR) (LiDAR) surveys are positioned using GNSS, as are many drone systems (see DRONES), albeit with varying levels of spatial precision. Equally, the integration of satellite-based navigation within a range of mobile computers and other devices has meant that GIS can usefully be taken out into the field for the checking, modification, and collection of data. From its use on mobile devices through to the integration of GIS software within surveying equipment, GNSS has provided archaeologists with a range of new potential applications. From facilitating interpretation in the field to ensuring that the digital record from fieldwork is correct, mobile GIS is breaking down barriers between the field and the office.

Archaeology is a spatial discipline and so advances in the ability to measure and record positions are of key value. Depending on the system and equipment being used, satellite-based navigation systems provide a variety of different levels of precision in relation to absolute positions. The ways in which this capability has been used are varied, although perhaps the most

exciting developments lie in the integration between positioning and other applications, such as geophysics and mobile GIS. While this all provides archaeologists with many new and exciting opportunities, there are of course potential limitations. For example, the expense of some of the survey grade systems can reduce their availability for many users, although this concern should be tempered by the great benefits of the recreational grade systems and their broad accessibility on mobile devices such as smartphones, as well as by the continued use of other survey techniques. Ultimately, the increased sophistication of systems such as GPS has made positioning and surveying within archaeology much simpler and less labor-intensive, and this is already allowing archaeological projects to become more efficient and ambitious.

Gradiometry

JARROD BURKS

Ohio Valley Archaeology, Inc., USA

Gradiometry is a type of magnetometry often used by archaeologists in which two magnetic sensors are attached to the same instrument (a gradiometer), usually one above the other. The spacing between the sensors varies, with 50 cm to 100 cm being common. During a typical gradiometer survey, the instrument uses simultaneous readings from each sensor to produce a single reading, the difference, at each data collection point. Like magnetometers, gradiometers are useful for detecting iron objects, burned earth (e.g., kilns, hearths, and house floors), and the accumulation of topsoil or archaeological midden in subsurface pits, trenches, and ditches.

There are at least two reasons why an instrument using two sensors (a gradiometer) is useful in archaeological contexts. The first and primary reason gradiometers are useful is for filtering out the daily fluctuations in the strength of the earth's magnetic field. The earth's magnetic field is all around us and it is constantly "turned on." Its intensity is recorded in units known as nanoteslas (nT), with stronger readings near the poles (over 60,000 nT) and weaker at the equator (below 30,000 nT). While the strength and positioning of the magnetic field generated by the earth is relatively stable, changing only slowly through time and across the planet (thus the utility of paleomagnetic dating), sources of magnetic disturbance from outside the earth, especially from solar flares, can create daily changes measuring hundreds of nanoteslas. Since these daily changes in magnetism are often as strong as or stronger than the magnetic signature of archaeological features, it is necessary to remove them when conducting archaeological surveys. Gradiometers filter out the daily magnetic field strength fluctuations by recording the difference between

the readings measured by each sensor. As the instrument is moved along the surface at a fixed height, and assuming the sensors are stacked one above the other, in principle the bottom sensor detects the earth's magnetic field plus any changes to it caused by archaeological features at or near the surface, while the top sensor detects just the earth's magnetic field. Subtracting the top sensor's reading from that of the bottom leaves the effects caused by things buried in the ground. Since daily fluctuations in the magnetic field are detected by both sensors equally, they are filtered out. A second reason gradiometers are useful in archaeology is they allow the surveyor to collect useful data closer to large iron objects, such as buildings, vehicles, and iron fences.

Gradiometers have been in use on archaeology sites for well over 50 years. Initially they were referred to as differential magnetometers (Aitken 1961), and the sensors were of the proton precession type. Today, archaeologists more often use gradiometers with fluxgate or cesium vapor sensors. The sensors in most fluxgate gradiometers are set at a fixed distance, ranging from 50 cm to 100 cm, while the sensors of cesium vapor systems are adjustable. Most gradiometers in use today can detect magnetic field differences of as little as 0.1 nT. A typical archaeological survey with a gradiometer may record eight to ten readings per meter along transects spaced 25 cm to 50 cm apart (for example, see Figure 1). Single and dual gradiometer systems are often carried; larger cart-based systems with three, four, five, ten, or more gradiometers are pushed or towed. Such towed systems can be used to cover vast areas, from 2 to 20 ha in a single day.

Ground-Penetrating Radar

LAWRENCE B. CONYERS
University of Denver, USA

Ground-penetrating radar (GPR) is a shallow geophysical technique that produces many different three-dimensional datasets of the buried materials. Buried units can be analyzed by interpreting many two-dimensional reflection profiles that are closely spaced within grids and larger scale map-view images. The method can be used to produce images of buried archaeological features and associated soils and sedimentary units within about 4–5 m of the ground surface, but sometimes deeper if ground conditions allow deeper radar energy penetration. It can be used as an exploration tool for finding buried archaeological sites, for projecting information from standard excavations into adjacent areas (Conyers 2013), and as a method for testing hypotheses about human behavior (Conyers 2010; Conyers and Leckebusch 2010) that relate to the placement of features on a buried landscape, or the shape, orientation, and placement of buried remains (Conyers 2009). It is particularly useful in geologically complex areas, where there are associated sedimentary layers and soil units associated with archaeological materials (Conyers 2016). When archaeological features can be discriminated and placed within a geological context, complex burial conditions and human remains within them can potentially be understood in three-dimensions.

The GPR method consists of measuring the elapsed time between when waves of electromagnetic (radar) energy are generated at a surface antenna, transmitted to depth, reflected from buried discontinuities, and then received and recorded at the surface. Reflection data are most often collected by moving antennas along the ground surface in transects, while energy is transmitted, reflected, and recorded in closely

spaced traces, with each trace being a record of reflected waves at one location. Traces are usually spaced between 3–5 cm along linear transects and reflections recorded within a pre-programmed time window (within two-way travel time, measured in nanoseconds). The distribution and orientation of reflections generated from layers and features of geological or archaeological importance are then identified and images are produced in two-dimensional profiles consisting of many hundreds of traces stacked vertically (Figure 1). When many profiles consisting of thousands, or hundreds of thousands, of reflections are resampled and oriented in three-dimensional space, images of reflections can be produced in amplitude slice-maps of any orientation (Figure 2) or three-dimensional visualizations of the stronger reflections called isosurfaces (Conyers 2013).

Production of radar reflections

When radar waves are transmitted from a surface antenna through various materials in the ground, their velocity changes, depending on the physical and chemical properties of the ground. Significant velocity changes often occur at interfaces between materials of different composition, water saturation, or mineralogy. When propagating radar energy abruptly changes velocity at interfaces, some is reflected back toward the surface, which is detected and recorded at a receiving surface antenna. The amplitude of recorded waves is proportional to the changes in velocity. When radar wave velocity is calculated, travel times can be converted to depth, and a three-dimensional dataset is produced. In this dataset, the amplitudes measure the relative differences in material type in the ground, and the travel time measures their depth below the surface.

Point source reflections often occur in the shape of hyperbolas (Figure 3). This shape is produced because most GPR antennas produce a transmitted radar beam that propagates downward from the surface in a conical pattern,

Figure 1 Two-dimensional reflection profile showing a buried pit house floor.

radiating outward as energy travels to depth. Radar waves will therefore be reflected from buried point sources that are not located directly below the transmitting antenna but are still within the propagating beam of moving waves. Oblique radar waves travel paths to and from the ground surface to point sources in the front and back of the antenna are longer (as measured in radar travel time) but the reflections generated are recorded as if they were directly below, but just deeper in the ground. As the surface antenna moves closer to a buried point source, the receiving antenna will continue to record reflections from the buried point source prior to arriving directly on top of it and continue to record reflections from it moving away. A reflection hyperbola is then generated with only the apex of the reflection denoting the actual location of the object in the ground, with the arms of the hyperbola creating a record of reflections that traveled the oblique wave paths. In some cases, only half of a hyperbola may be recorded, if just the corner or edge of a more planar feature is causing a discrete reflection, such as the edge of a buried house floor or platform. The shape of hyperbolas can also be used to calculate radar travel velocity in the ground (Conyers 2013). Hyperbola analysis is therefore an extremely efficient and accurate way to convert all radar travel times to depth in the ground.

Variables affecting GPR

The success of GPR surveys depends on soil and sediment mineralogy, clay content, ground moisture, depth of burial, surface topography, and vegetation. Radar wave penetration, and the ability to transmit energy through the ground and reflect it back to the surface, are often enhanced in a dry environment, but dry conditions are not necessarily a prerequisite, as surveys in wet environments can be successful as long as the media in the ground are not electrically conductive. The mineralogy of materials in the ground is also important, especially clay type and content. Sediments that contain electrically resistive clay minerals, such as kaolinite, are excellent at allowing the transmission of radar waves, while bentonite, montmorillonite, and other electrically conductive clays are generally poor for transmission, as radar energy is conducted away and propagation of waves ceases. Fresh water is an excellent medium for radar energy transmission, and the propagating waves can travel to great depths in lakes and especially through glacial ice. However, when fresh water comes in contact with electrically conductive materials, attenuation of the propagating energy occurs. Salty or brackish water will not allow radar energy transmission to any depth.

The depth to which radar energy can penetrate and the amount of definition that can be expected from reflections generated at buried surfaces is partially controlled by the frequency of radar

Figure 2 Horizontal amplitude slice maps showing a buried Roman temple.

energy transmitted, which is a function of the antenna used. Standard GPR antennas propagate radar energy ranging in band width from about 10 to 1200 megahertz (MHz). In general, lower-frequency waves propagate deeper into the ground, but have less subsurface resolution. For instance, 200 MHz antennas can potentially transmit energy to 4 or 5 m depth, but reflections are generated only from large features, in the order of a meter or so in dimension. A higher-frequency 900 MHz antenna can potentially resolve features in the order of 10–20 cm in maximum dimension, but is capable of energy transmission to about a meter or less in the ground. In electrically conductive ground all radar energy, no matter what frequency, will attenuate at a very shallow depth.

Radar energy becomes both dispersed and attenuated as waves move into the ground from surface antennas. Energy that is reflected back toward the surface will suffer additional attenuation by the material through which they pass, before finally being recorded at the surface antenna. Therefore to be detected as reflections, important subsurface interfaces must not only have sufficient electrical contrast at their boundary but also must be located at a shallow enough depth where sufficient radar energy is still available for reflection. As radar energy is propagated to increasing depths, the signal becomes weaker as it spreads out over more surface area and is absorbed by the ground, making less available for reflection. For every site the maximum depth of resolution will vary with the geologic conditions and the equipment being used.

GPR images

Radar reflection profiles are the most basic form of data presentation, which show distance along transects on the horizontal scale and depth in the ground where reflections of varying amplitude were recorded on the vertical axis (see Figure 1). Depth is recorded in two-way travel time, but can be converted to depth, if the propagating wave velocity is calculated. If the ground is stratigraphically simple, and buried archaeological features are distinct, they can be readily viewed, mapped, and interpreted

Figure 3 Hyperbolic reflections displayed in profile, generated from individual objects in the ground.

in profile form. However, when many tens or hundreds of profiles are collected in grids, individual profile interpretation can be laborious, and the three-dimensional aspects of reflections are difficult to image and understand and differentiate from other geological units. To overcome this complexity of an overwhelming amount of data in three-dimensional space, slice-maps that produce images of relative amplitudes of reflected waves throughout a grid of reflection profiles can be produced (see Figure 2). These types of maps are generated by sampling, gridding, and averaging all waves in all reflection profiles in a grid and displaying various amplitudes in defined slices of any thickness or orientation. Different amplitudes are then colored, corresponding to the location of buried materials of interest. In geologically complex areas, stratigraphic layers will generate high-amplitude reflections as well as those of archaeological features and can be misinterpreted unless there is an understanding of the nature of all strata (Conyers 2016). Simpler ground conditions, however, will allow the reflection amplitudes of buried archaeological features to be readily imaged in both profiles and amplitude maps.

There has always been a bias in GPR toward analyzing and mapping only the higher-amplitude reflections, but areas of low or no amplitude can also be important. If buried archaeological features of interest do not reflect radar waves, such as uniform earthen architecture, they can still be

imaged and interpreted as zones in profiles and maps with no, or only low, amplitudes (Conyers 2013). Only an understanding of the reflectivity of the various materials in the ground will allow accurate interpretation of GPR images.

Complexities in GPR interpretation

If the geological materials in the ground are complexly bedded, the computer sampling methods for amplitude mapping will display reflection amplitudes from one continuous horizon as if it was a series of aurally restricted “anomalies” at various depths within each slice. As the layers in the ground are dipping, most GPR processing software used to generate three-dimensional images will generate extraordinarily busy “anomaly” maps that are mostly irrelevant to the final interpretation as slices cross horizons at various depths. The amplitude maps are then imaging only bedding horizons that may be located in any one slice. Any archaeological features within this package of bedded material will be effectively hidden within the final images. In this case only an understanding of the basic reflection information from which the images are produced within a geological context (Conyers 2016) will allow an accurate final product.

Another basic question with GPR interpretation (Conyers 2012) is what may be producing the reflections in a dataset. Often this can only

be determined from viewing reflections in profiles and understanding what produces radar reflections and then correlating those directly to excavations or other information about the ground. These basic interpretations make sense as interfaces between archaeological materials and surrounding sediments and soils that produce the high amplitude reflections can be understood. For instance, in an area with buried homogeneous clay walls and floors, only the horizontal floors are visible in GPR profiles with the walls being nonreflective as they are composed of clay and other fine-grained materials with no interior bedding planes or other interfaces from which to reflect energy. Any vertical interfaces between the walls and surrounding materials are also not reflective, as radar waves transmitted from the surface move parallel to these vertical boundaries, or if radar waves intersect the interfaces they are reflected away from the surface recording antenna and not recorded. When viewed in reflection profiles the vertical clay walls appear as areas of no reflection and unless an interpreter understands the nature of the materials in the ground these features will often go unnoticed.

Using GPR for archaeological interpretation

Archaeological geophysics is often used as a method for discovering buried archaeological remains and less often as a dataset for interpreting aspects of human history and anthropological hypotheses relating to culture. However, GPR with its three-dimensional mapping ability, can be used to test ideas about humans in ways that are similar to standard archaeological methods (Conyers 2010; Conyers and Leckebusch 2010). If architecture, site organization, or any aspects of human modification and archaeological remains on the landscape GPR can be an excellent tool (Conyers 2009). The GPR method can be an especially powerful tool when combined with standard archaeological excavations, especially when the geophysical images can be used as a guide to the placement of subsurface tests that test ideas of interest.

Ground-penetrating radar has the unique ability of near-surface geophysical methods to produce three-dimensional maps and images of buried architecture and other associated cultural and natural features. It can be performed in any type of ground, as long as the sediments and soils are not highly electrically conductive. Using high-definition two-dimensional reflection profiles, three-dimensional maps of amplitude changes can define physical and chemical changes in the ground that are related to archaeological and geological materials of importance. Interpretations that use individual two-dimensional reflection profiles combined with images of grids of many tens or hundreds of profiles can be used to help understand buried archaeological sites, especially those that are geologically complex. When these data and maps are used to test ideas about human adaptation to ancient landscapes, they offer a powerful and time-efficient way to study ancient human behavior, social organization, and other important archaeological and historical concepts.

IR Thermography

CARLO SANTULLI and ROBERTA COCCI
GRIFONI

Università degli Studi di Camerino, Italy

Introduction

IR thermography (IRT) is a non-destructive inspection technique that measures the electromagnetic energy emitted from a surface in the infrared (IR) radiation band, which is normally referred to as thermal radiation. By measuring the emissivity of the surface, which depends mainly on its color and on the reflectivity of the surrounding environment, it converts the thermal radiation to temperature, and therefore is able to display temperature distribution, which is represented as an image in false colors. Information is obtained by building on the fact that the radiation effect is closely correlated to the temperature of the radiating object. This is possible since thermography provides temperature monitoring of different sample surface areas, allowing a time-resolved analysis of the heat diffusion process in the sample including its subsurface structure. As regards these measurements, disturbance effects are offered by air temperature, solar radiation, and plant physiological parameters.

Applications of IRT are widespread in various fields from science, civil and military industries to medical diagnostics, fire rescue and maintenance, and so on, in some cases offering indications, normally over a very short timeframe, of the effect of the application of a stress (mechanical or thermal). The duration of the thermal stress introduced can in some cases be very short, so that it can be described as a pulse ("pulse thermography"). Lockin thermography, where the infrared wave signal is produced in response to an excitation, normally created by eddy current or ultrasound techniques, has recently generated interest for archaeological surveys.

Thermal radiation can simply be produced as the effect of illumination of the surface, in some cases barely, by solar light. The hidden assumption in this case is that the differences in thermal radiation are offered by structural differences in the surface properties or even at some depth below the surface, so that considerations can be made on the presence of different structures, which are not visible to the naked eye. In particular, the passive use of IRT is quite widespread in the inspection of a number of artifacts, including engineered structures and surfaces. The application of this technique is based on the assumption that parts with different properties emit different amounts of energy. In the case of historical buildings, it is possible to detect cracks, de-adhesion, for example of plaster from the wall, alteration of material consistency, and so on. In particular, by selecting the most adequate thermographic technique, it is possible to monitor the conservation state of artworks in time, and detect the presence of defects in different types of materials, such as concrete, masonry structures, or bronze.

In general terms, IR thermography is able to reveal features with sufficient contrast in thermal inertia within the complex of materials of which they are composed. Thermal inertia can be defined as the product of thermal conductivity and volumetric heat capacity of a material. To improve the quality of the image, these are repeatedly acquired during periods of the diurnal cycle where such contrast is the highest.

Archaeological thermography

IR thermography can be used as a remote sensing tool to identify, evaluate, document, and assess cultural resources. Analyzing surface temperature rates of change and their spatial variations allows not only evaluation of the incidence of thermal decay on the whole phenomenon of stone decay, but also other factors affecting the state of conservation of architectural and archaeological

heritage such as moisture, salts, or mechanical disruption. This is effective for brick, stone, and mortar, but less so for wood with its lower heat capacity.

Aerial thermography, normally making use of IR wavelengths between 8–14 microns and acquired together with panchromatic photographs (at shorter wavelengths), originally applied to the presence of ancient cropping areas for its ability to reveal surface and subsurface cultural features, has also been proved as a survey method for archaeological sites. Another possibility that has been more recently explored is the use of kite-driven aerial thermography to reveal many subsurface remains, such as at a mound center in Mississippi (Haley, Johnson, and Stallings 2002). Here, thermal imagery was able to document subsurface house remains, in particular revealing ellipses of daub, a brick-like material produced when houses were burnt to make space for new constructions. The diurnal variation in their thermal values was acquired, by recording sunrise and sunset times. Several recent studies have explored the archaeological potential of much higher resolution thermal images. For example, Ben-Dor et al. (2001) collected imagery from a helicopter to detect subsurface stone architecture from an altitude of 1,333 metres over the Golan Heights in Israel, while Buck, Sabol, and Gillespie (2003) used thermal images collected by a camera mounted on a platform to reveal differing concentrations of surface artifacts, such as obsidian pottery.

Limitations to archaeological thermography occur in the presence of vegetation, which may confuse the image, so that vegetation temperature is better monitored separately. Thermography can detect features at or near the ground surface, such as pits, ditches, and field boundaries, as well as buried architectural features up to half a meter below ground (Bellerby, Noel, and Branigan 1990). More recently, the availability of multispectral methods of airborne remote sensing allows the measurement of vegetation indices, including crop variation (Challis, Kincey, and Howard 2009).

Further possibilities are offered by the combined use of IRT with ground-penetrating radar (GPR), employed together for the in-situ inspection of Pompeii and Nora (Carlomagno et al.

2011). IRT is also capable of elucidating the state of bonding between plaster and its support in Roman masonry, offering a clear view of the construction details concealed under the finishing layer, such as the shape and layout of the masonry units (Colla et al. 2008). In the case of marble structures, especially when trying to measure the surface roughness, which may be useful to elucidate the history of the artifact, promising characteristics were also indicated by the combined use of 3D profilometry with pulsed thermography (Avdelidis et al. 2004).

At a larger scale of inspection, two seasons of aerial surveys at Double Ditch archaeological site offered complete coverage by digital color video, high-resolution color stills, and thermal imaging in the 10 microns band, acquiring data from a low- and slow-flying powered parachute platform, 250–500 m above the ground. IRT was used as an essential part of complete geophysical surveys, which included magnetic gradiometry and electrical resistivity methods, and large areas of ground-penetrating radar (GPR) and electromagnetic induction surveys (Kvamme, Ernenwein, and Markussen 2006). The application of IRT in combination with other techniques, such as high-frequency electromagnetic techniques (GPR) for the survey of archaeological sites, allow surveys on land at a shorter distance and with higher resolution. IRT could be used in the first instance to supply a 2D map, which would include detailed information about surface and shallow anomalies. Then GPR could offer a broader 3D description of the horizontal and depth position of features and defects, allowing the survey to descend to greater depths. However, this appears to be very challenging, requiring a microlight aircraft with an experienced pilot, ideal weather conditions, and very time-consuming image processing work to rectify and mosaic the images into a usable map.

For this reason, most recently the use of unmanned aerial vehicles (UAVs) has also been proposed, with methods such as airborne thermal prospecting based on the difference between the thermal characteristics of buried remains and the environment in which they are buried, and integrating thermal cameras into the UAV structure, with further processing through photogrammetry software (Poirier, Hautefeuille, and Calastrenc

2013). Aerial surveys at the Chaco-period Blue J community in northwestern New Mexico enabled easy mapping of the size and organization of most habitation sites, while also revealing previously undocumented architectural features (Casana et al. 2014).

Future perspectives

Interest in IRT for archaeological inspection at different scales, from that of walls and artifacts to the wider assessment of a whole archaeological site, is rapidly growing. This is due to both the decrease in cost of the available thermal cameras, as well as rapid improvements with regard to spatial resolution (reaching levels of 1024×768 for most recent models), while substantially fine-tuning thermal resolution almost to the level of K/100. At the same time, advances in photogrammetric image processing software packages allow easier composition of images into a coherent picture of the archaeological site. This is coupled with the combined use of different techniques, including ground-penetrating radar, while improvements in aerial thermography have come from the development of more reliable unmanned aerial vehicles.

Magnetic Field Gradient

LUIS M. ALVA-VALDIVIA and A. AGARWAL
Universidad Nacional Autónoma de México, Mexico

Study of the magnetic field gradient for archaeological prospecting involves measurements of the Earth's magnetic field on a regular or irregular grid of observation points at the investigated site (Aitken 1958). Survey of magnetic gradient is a nondestructive method employing measurement of the total magnetic field. It allows effective implementation of prospection during archaeological planning for excavations (Eppelbaum, Itkis, and Petrov 2000) and facilitates rapid outlining of the archaeological potentialities in the investigated zone. Such investigations are most commonly coupled with additional information on geology and (archaeo-) morphology to better characterize the areas with high archaeological potential. In special cases, these are used as an alternative to excavations to avoid site destruction (Eppelbaum et al. 2000).

Most modern instruments have evolved from either the fluxgate or optically pumped technology. These modern instruments have impressive speed in the field, due to automatic data recording and use of mechanically efficient methods of towing (Becker 1999). Recent studies have showcased detailed maps conspicuously depicting buried archaeological features such as ancient cities, and pre- and protohistoric anthropogenic elements, such as pits and ditches (Aubry et al. 2001).

Methodology

Prior to starting the archaeomagnetic survey, it is critical to investigate the quaternary geological landforms (lithology, topography) covering the archaeological sites (Aubry et al. 2001). This investigation delineates the natural background signal. Natural processes and anthropogenic

activities may enhance or lessen the magnetic signals. These processes include pedogenesis (which may cause intense transformations of soil), agriculture, forestry, deforestation due to natural or anthropogenic fire, and transportation of sediments and rocks down the slope. In summary, a careful estimation of the site is critical for an effective detection and interpretation of the archaeological feature.

A conspicuous detection further depends on the mesh size, investigation depth, and archaeological nature of the feature, such as kilns (distinct magnetic field gradient) and caves (weak magnetic field gradient). For archaeomagnetic prospecting, spatial resolution, sensitivity, and speed are highly desired (Becker 1999). Spatial resolution is determined by the step size in the sampling mesh. Generally, the step size is between 5 and 20 m. Such mesh allows a rapid and effective survey. Notably, the probability of detection of a feature is more if its diameter is at least twice the size of the step in the sampling mesh. In recent times, there has been a shift away from pre-gridded surveys towards real-time global positioning system (GPS) navigation. This allows greater integration and visualization of disparate data, along with precise data location that increases the quality and reduces processing (Gaffney 2008).

The backbone of high-sensitivity magnetic prospecting is the reduction of the natural and technical temporal geomagnetic variations caused by micropulsations, power lines, and so on. This may be achieved by measuring the difference between two sensors in vertical gradiometer or variometer mode (Becker 1999). Thereafter, the readings are corrected for changes in the ambient field, caused by diurnal variations and magnetic storms.

An archaeological geophysicist has a variety of magnetometers and instrumental setups to choose from: vertical or total field, a single sensor, gradiometer or differential mode, handheld or nonmagnetic cart, human- or vehicle-powered. The most frequently employed magnetometers are: (1) proton instruments,

(2) vapor magnetometers, (3) fluxgate gradiometers, and (4) superconducting quantum interference device (SQUID).

Proton instruments were the earliest magnetometers used for surveying magnetic field gradient for archaeological purposes. They made magnetic prospecting practicable in archaeology. They have inherent advantages, such as absolute reading without calibration and directional sensitivity, and no requirement for a setting-up procedure due to high-precision construction. Nevertheless, due to their polarization-measurement mode of operation, they are much slower than the latest instruments and are less adapted for rapid archaeological surveys that demand speedy gathering of high-density information (Clark 2003).

The alkali vapor magnetometer (cesium or rubidium) is a highly sensitive instrument. The University of Pennsylvania Museum of Archaeology and Anthropology initiated its archaeological use. These magnetometers have the advantage of producing an effectively continuous signal and can be used in the differential form, but they are expensive and prone to breaking down because of their complexity (Clark 2003). For normal archaeological prospecting, their high resolution (~ 0.01 nT) rarely has a practical advantage over fluxgate and proton instruments with 0.1 nT resolution.

The fluxgate gradiometer is the most used instrument for archaeomagnetic prospecting. Two sensors are mounted, with their axes vertical, on a vertical pole separated by a distance of 1.2 m. The outputs of the two sensors are subtracted from each other to obtain the resultant. The resultant is governed by the vector addition of the two contributions, such that $(B_{\text{Earth}} + B_{\text{Anomaly}}) - B_{\text{Earth}} \approx B_{\text{Anomaly}} \times e_{\text{Earth}}$, where e_{Earth} is the unit vector in the direction of the Earth's magnetic field (Blakely 1996). In cases where the Earth's magnetic field is undisturbed, the resultant is zero; however, when it is disturbed by a buried archaeological feature the resultant is nonzero. For interpretation, the resultant is amplified and fed to a phase-sensitive detector. The gradiometer suffers from a slight disadvantage due to the cyclic mode of operation, where each individual reading is separated by a pause of a few seconds.

SQUID measures true gradients of the magnetic field with high sensitivity, in the order of 10^{-15} nT. Its inherent advantage of high sensitivity is complemented by the incredible data acquisition rate that allows traversing at high speeds of 30 km/h. Although SQUID outperforms other magnetometers, it has two major limitations. It must be kept very cold for effective superconductivity, and it has a short baseline, which is essential to suppress the Earth's field and the field from other nearby mechanical devices. Nevertheless, SQUID field systems are being used for archaeomagnetic prospecting (Linzen et al. 2007).

Advantages of archaeomagnetic prospecting over traditional techniques

Archaeomagnetic prospecting is rapid and inexpensive. Thus, it is often used to survey and rescue probable archaeological sites in areas that are currently under intense pressure from urban development (Aubry et al. 2001; Bates, Bates, and Whittaker 2007). Inexpensive archaeomagnetic prospecting is preferred over traditional expensive survey through boreholes or trenches. This is particularly the case where the overlying deposits are more than 5 m thick and are composed of hard sand and clay, or gravels (Bates et al. 2007). Besides the financial consideration, archaeomagnetic prospecting surpasses traditional borehole survey because the data are collected rapidly, with high density, and are largely free from periodic errors (Gaffney 2008). Archaeomagnetic prospecting does not disturb the soil or cause damage. In contrast, after archaeological excavation, sites are prone to weathering and vandalism. Furthermore, excavation itself implies destruction. Among all geophysical techniques, archaeomagnetic prospecting is most suitable for identifying pits, wells, ditches, and any other types of backfilled features in the open field; and it is exclusively applied for kilns, slag deposits, and other features related to intensive use of fire (Aubry et al. 2001).

Shortcomings of archaeomagnetic prospecting

Archaeomagnetic prospecting, by studying magnetic field gradient, is less suitable than the resistivity method for identifying stone and brick buildings, roads and urban networks, and surrounding walls. Similarly, electromagnetic methods are preferred for detection of metal objects. Hollow spaces, such as caves and tombs, are generally difficult to investigate, especially when their height exceeds the other two dimensions. Such features demand a combination of several geophysical techniques.

Estimation of the depth of features is essential, as it helps to evaluate the potential difficulties and cost of a scheduled excavation. However, determination of the depth, from magnetic field gradient, is tricky. Moreover, numerous natural and artificial noises interfere with the magnetic signals. The most harmful factor is the oblique magnetization in some parts of the world. For example, the inclination of the Earth's magnetization vector in Israel is about 45° . Other factors include complex geological structures and the influence of modern iron-containing objects (Eppelbaum et al. 2000).

In summary, magnetic field gradient provides a robust, rapid, and economic procedure for archaeological prospecting. Depending upon the objectives, it may yield a preliminary perspective of the buried feature or a detailed view, which may be used as an alternative to excavations to avoid site destruction.

Olmec monumental elements: case study

We studied the magnetic field gradient in the San Lorenzo Tenochtitlán, a lowland area of southern Veracruz, Mexico ($17^\circ 45' 24''$ N and $94^\circ 45' 42''$ W). The objective was to explore specific selected areas for structures, monuments, and archaeological pieces of Olmec art such as colossal heads, thrones, massive altars, and animal figures. (Figure 1). The Olmec were perhaps one of the oldest and greatest societies in Mesoamerica. The archaeological pieces are commonly carved from volcanic rocks, such as basalt, that probably came from rock outcrops,

Figure 1 Olmec colossal head (weighs between 6 and 50 tons), sculpted in ca. 1500–400 BCE. Source: Picture provided by Ann Cyphers.

approximately 60 km northwest of San Lorenzo. The contrast in the rock magnetic properties between the volcanic rocks and the enveloping soil cover makes this method most suitable.

We used the Gradiometer G-856 for the magnetic fieldwork, measuring with a 1-m step size along 100-m-long lines. A gradiometer setup (sensors separated by 0.79 m) was used to acquire two measurements at each step (one from each sensor). The data acquired were edited, corrected for inaccuracies during acquisition, and processed in the Magloc program supplied by EG&G Geometrics. Magloc provides a summary data grid, as the amplitude of the magnetic anomalies (Figure 2) (Oropeza-Villalobos 1999).

In cases where an area of interest is identified in the magnetic anomaly map, we used the separated anomaly to make a quantitative evaluation (magnetic modeling, using Oasis Montaj-GMSYS software) to identify the location, depth, shape, and size of the magnetic bodies (for detailed methodology see Grant and West 1965). This allowed us to locate unfinished colossal heads weighing around 20 tons. This discovery was archaeologically relevant to expand the basic knowledge of the Olmec society that prospered during the Preclassic period.

Figure 2 Three-dimensional representation of data from the magnetometer (left). Anomaly magnetic map generated after applying the second derivative (right). Areas of interest are marked with two black rectangles.

Magnetic Susceptibility

LUIS M. ALVA-VALDIVIA and A. AGARWAL
Universidad Nacional Autónoma de México, Mexico

T. CRUZ-Y-CRUZ
Escuela Nacional de Antropología e Historia, Mexico

Magnetic susceptibility (K) is a dimensionless quantity that indicates the degree of magnetization in a material in response to an applied magnetic field. It is important to note that for most of the rock magnetic measurements applicable in archaeology, K is measured at the low applied magnetic field. K of a material depends, most importantly, on the mineralogy. Ferromagnetic minerals, such as magnetite, have high K ($> 10^{-3}$ SI units), while paramagnetic minerals, such as chlorite, have K in the order of 10^{-6} SI units. Diamagnetic minerals, such as quartzite, and most organic materials have $K < 0$ SI units. Thus, measurement of K in natural conditions may provide basic information on the mineralogy, whereas measurement and comparison of K in different ambient conditions reveals precise information on the magnetic mineralogy. This information, when coupled with additional archaeological, geological, and geographical information, provides important details about ancient societies.

Measurement of bulk magnetic susceptibility

The most common methods used reveal K under various ambient conditions. Such methods are very reliable, as they provide clues to magnetic mineralogy and domain size. These methods are as follows.

K of soils and archaeological artifacts may be measured in situ (without physically disturbing) or with samples in the laboratory. There are numerous handheld portable susceptibility

meters available such as SM-30 (Heritage Geophysics) and MS3 (Bartington Instruments). They provide rapid measurements at a unique frequency at room temperature. For more precise measurements, using laboratory-based instruments, there is the MFK-1 (AGICO). It facilitates measurement of K under various ambient conditions, such as high or low temperature, and an applied magnetic or electric field of a constant or varying frequency and strength.

Thermomagnetic curves are plotted by measuring K at various temperatures, usually from -192 to 700°C . K of each mineral has a characteristic relationship with temperature, which depends on the mineral's magnetic grain size and chemical composition. A slight variation in either changes the characteristic shape of the thermomagnetic curve. These curves therefore provide quantitative magnetic mineralogy, such as the content of Ti in magnetite or in maghemite, and qualitative information on the magnetic domain size (e.g., Agarwal, Kontny, and Greiling 2015; Agarwal et al. 2016; Alva-Valdivia et al. 2017).

Hysteresis curves are plotted by measuring the magnetic moment in a variable applied magnetic field. The shape of a hysteresis curve provides quantitative information about the magnetic grain. Modern instruments have the capability of combining the thermomagnetic and hysteresis curves, by enabling measurement of the magnetic moment in varying fields and at various temperatures.

Gathering additional information

Complete and effective archaeological interpretation demands careful study of the geological character of the area, such as paleogeography. For example, in the case of paleosols it is critical to understand the natural pedogenesis in the area. Similarly, in the case of archaeological artifacts made of various rocks and ores it is important to understand the geological setting of the nearby rock formations.

As discussed earlier, K depends on several factors. Arguably, the most important is the mineralogy. Therefore, rock magnetic methods are usually coupled with additional chemical investigations for effective interpretation. The most common methods for determining mineralogy and chemical composition are X-ray fluorescence (XRF), wavelength dispersive spectroscopy (WDS), energy dispersive X-ray (EDX), inductively coupled plasma mass spectroscopy (ICP-MS), and atomic absorption spectroscopy (AAS).

Case study 1: Identification of anthropogenic activity in La Playa, Sonora, Mexico

The archaeological site of La Playa, Sonora, shows conspicuous evidence of human occupation since the Late Pleistocene. However, the society reached its peak in the Late Holocene, ca. 3,500 years ago (Carpenter et al. 2015). The site is spread over an area of about 10 km², over an alluvial fan formed in the foothills of the Sierra Boquillas (Carpenter et al. 2015).

Two pedosedimentary profiles are described in the area: the 14,570 ± 340-year-old San Rafael Paleosol (SRP) and 3,985 ± 105-year-old Boquillas Paleosol (BOP) (Cruz-y-Cruz et al. 2014). Samples were collected for identification, description, and classification of soil horizons. Free iron (Fe_d) was separated (for technique see Mehra and Jackson 1960), and AAS was performed using the Perkin Elmer Model 3110 in the Department of Soil Science, Institute of Geology, UNAM. For measuring K , samples were collected every 10 cm in the entire profile and dried at room temperature and placed in plastic cubes of 8 cm³. K at low and high frequency (LF and HF) was measured with a Bartington MS2 susceptibility meter in the Institute of Geophysics, UNAM.

In SRP, K displays conspicuous maxima at 2Bw and minima at 3Bgk horizons (Cruz-y-Cruz et al. 2014, Figure 1). These maxima and minima correlate well with the maximum and minimum values of Fe_d in the SRP paleosol. The correlation is owing to pedogenesis, which commonly leads to the formation of ferrimagnetic minerals, such as

magnetite, causing an increase in Fe_d and accordingly in K .

The situation in BOP is far more interesting. Horizon C has highest K , while horizons 3A and 3C present least K (Cruz-y-Cruz et al. 2014, Figure 1). As expected, horizon 3C has low Fe_d. In contrast, horizons C and 3A present a reverse correlation between K and Fe_d, with very low and mid-levels of Fe_d, respectively. This reverse correlation is owing to the production of ferrimagnetic minerals by the intense burning in ovens. In agreement, Carpenter et al. (2015) suggest that the ancient group built over 1,500 ovens in the area.

In summary, the study of K allowed identification of anthropogenic ferrimagnetic phases, which consecutively revealed the probable location of ancient ovens (Cruz-y-Cruz et al. 2014).

Case study 2: Source of multiperforated Olmec artifacts

The Olmec arose and flourished on Mexico's southern Gulf Coast between 1800 and 400 BC, and developed extensive trade relationships for procurement of exotic materials from distant regions. Magnetic susceptibility was used to determine the source locality of archaeological artifacts which Olmec society used as drill bearings (Alva-Valdivia et al. 2017). About three tons of the multiperforated artifacts were found at the archaeological site of San Lorenzo in southern Veracruz, Mexico (e.g., Cyphers and Di Castro 1996; Di Castro 1997). The artifacts are small and roughly cuboidal, with 2- to 3-cm-long edges. The artifacts have flat to slightly convex faces and rounded edges (Alva-Valdivia et al. 2017, Figure 2). Each artifact has three intentionally drilled conical perforations that developed when the artifacts were used as drill bearing.

The artifacts are comprised of iron ore. To determine the source of the artifacts, their rock magnetic properties (thermomagnetic and hysteresis curves) are compared with similar rock types exposed in the vicinity (several hundred kilometers) of San Lorenzo. These exposures are (1) Huitzo, Oaxaca, located in the Etla Valley; and (2) the volcanic-plutonic metamorphic complex of southeastern Chiapas in Motozintla.

Notably, the cooling and heating branches of the thermomagnetic curve of the Olmec and Huitzo samples are very similar, both partly reversible and partly irreversible (Alva-Valdivia et al. 2017, Figure 9). In contrast, the shape of the Motozintla curves (heating-cooling) and the range of magnetic susceptibility values are different from the Olmec artifacts (Alva-Valdivia et al. 2017, Figure 2). The wasp-waisted hysteresis curves are symmetrical for all samples and show a strong paramagnetic contribution. The Olmec and Huitzo samples have a remarkably high magnetic moment. Moreover, the two curves have very similar shape, in contrast to the Motozintla samples. Therefore, it is concluded that the Olmec artifacts are related to the Huitzo, rather than the Motozintla.

Case study 3: Archaeointensity dating: mineral phase changes in clay artifacts during heating

The importance for archaeological research to discern the chronological succession of events within the social dynamics of past populations is well recognized, because this knowledge allows understanding of the diverse social processes. Radiocarbon dating is the most common method to determine the age, if archaeologists can find the proper material to be analyzed. Alternatively, since the 1980s, archaeomagnetic dating started to be successfully applied. This method is characterized by age estimation in a high-precision confidence interval (combination of precision and accuracy). Besides, the determined age is related to an object or event of cultural importance that constitutes its great sturdiness.

The archaeointensity method is based on the fact that the magnetic minerals contained in clay acquire a thermal remanent magnetization when these are cooled in the presence of a magnetic field, after being heated to high temperatures. These temperatures reach the Curie temperature of the minerals, which depend on the cooking method for the ceramic.

To reach acceptable values of archaeointensity, it is essential that the artifact does not change its mineralogy during the heating

processes (one of the quality criteria that should be accomplished before attempting the extremely sophisticated archaeointensity experiment). Then, the thermomagnetic curves reveal the possible mineralogical changes. In the best-case scenario, they should be reversible during the heating-cooling branches, thus assessing that no changes in mineralogy are produced. After confirming a unique magnetic component during the thermal demagnetization processes in the artifact (another important quality criteria), it is almost certain that the archaeointensity experiment will successfully provide a reliable value of the intensity of the magnetic field at the time of the last heating of the artifact. Finally, comparison of these values with the secular variation curve of the magnetic intensity of the region (1,000-km-diameter area) reveals the age of the last heating.

Consequently, in many cases the archaeomagnetic ages will be much more useful than others. Therefore, archaeological ages will supply a scheme of the sequence of events at a single site or in a single region. Thus, the capacity to provide information with respect to stability and changes in the cultural and natural parameters through time is particularly important.

Magnetometry

JARROD BURKS

Ohio Valley Archaeology, Inc., USA

Magnetometry is the detection and study of archaeological deposits using instruments known as magnetometers (Figure 1), which record in units of nanoteslas, or nT for short. Magnetometers are useful for detecting objects, especially those made of iron, and various types of archaeological features that magnetically contrast with the sediments that surround them. Other metals such as aluminum, lead, silver, and gold are not magnetic. Understanding magnetometry and its application in archaeology can be broken down into three subtopics: magnetism, magnetometers and how they work, and the magnetic characteristics of archaeological sediments and features.

Magnetism

Magnetic fields have direction and magnitude, and they are often depicted as contour maps and as lines with small arrows indicating direction. The Earth's magnetic field is much like that of a bar magnetic, with north and south poles. Its direction and strength varies considerably depending on location. At the north and south poles the magnetic field lines are nearly vertical, while around the equator they are horizontal. In Figure 2 (top), the angled lines represent the Earth's magnetic field, which in this case is angled downward steeply. When two different magnetic fields intersect, they combine to either cancel each other out or increase or decrease the overall magnetic strength at that location. Iron objects, certain kinds of rocks (e.g., basalt, an igneous rock) and intensely heated iron-rich sediments (e.g., the bottoms of hearths) all have their own magnetic fields. These distinct magnetic fields combine with that of the Earth to create a total field strength. In the Figure 2 image (bottom), the magnetic fields of several different materials

are shown as distinct from the Earth's field for the sake of illustration. In reality, they would be combined with the Earth's magnetic field, creating localized magnetic anomalies that can be detected by a magnetometer. The magnitude of the Earth's magnetic field varies as well, ranging from about 30,000 nT to 60,000 nT depending on location (Lowrie 2007). This can vary daily by up to 100–200 nT due to the influence of charged particles ejected from the sun. These geographic and daily sources of magnetic variation are important to account for since archaeological features typically are quite weak in comparison, ranging from 1 to 100 nT in strength. And on some sites, significant features have been detected down in the 0.1–0.01 nT range.

There are two kinds of magnetization detectable with a magnetometer: thermoremanent magnetization and magnetic susceptibility. When iron-rich sediments and rocks are heated above a certain temperature, known as the Curie temperature (ca. 500–700 °C) (Lowrie 2007), they can become permanently magnetized—what is known as thermoremanent, or permanent, magnetization. At temperatures below the Curie point, an iron mineral's magnetic alignment is fixed. Once the mineral's temperature is high enough, its magnetic alignment is free to change and it becomes realigned to the strongest magnetic field in the area, which usually is the Earth's magnetic field. Campfires and trash burning can produce more than enough heat to reach the Curie point. Intense heating can make an otherwise magnetically neutral (i.e., minerals with random magnetic alignments) patch of ground highly magnetic through magnetic realignment; it can also transform less magnetic iron oxides (e.g., hematite) into more magnetic types (e.g., magnetite and maghemite). The resulting changes in magnetism are long lasting. Even sediments that have been disturbed and redeposited, such as by sweeping, plowing, or other kinds of earth moving, can maintain at least some of their permanent magnetization, which is not reset until the sediments are once again heated up to a point above the Curie temperature. Objects and sediments that are permanently magnetic do not

DOI: 10.1002/9781119188230.saseas0355

Figure 1 Components of a magnetometer, in this case a fluxgate gradiometer. Gradiometers record the difference between their two sensors, which helps to (1) filter out daily fluctuations in the Earth's magnetic field, and (2) lessen the influence of strong magnetic fields nearby.

require the presence of an outside magnetic field to be detectable, unlike those materials that are magnetic because of their magnetic susceptibility.

Soils and magnetic substances that have high *magnetic susceptibility* react when they are in the presence of a magnetic field. On archaeological sites it is the Earth's own magnetic field that causes these magnetic reactions. Certain soil horizons and components of soil, such as organic-rich topsoil (A horizon), are generally more susceptible to magnetic fields than deeper soil horizons, such as Bt (i.e., subsoil) horizons (Evans and Heller 2003). This can be a very useful principle on many kinds of archaeology sites, where the most common kind of archaeological feature is the pit feature—a hole dug into the ground that has been filled with topsoil or site midden and refuse. The Earth's magnetic field tends to be stronger in features with elevated susceptibility (as in the earth oven in Figure 2) and it is weaker in materials with low susceptibility (such as the limestone foundation stones in Figure 2). Furthermore, human occupation of an area enhances a soil's magnetic susceptibility (Dalan and Banerjee 1998). While the mechanisms behind enhancement are complex and

not totally understood, bacteria that use and produce small magnetic particles contribute to the process (Fassbinder, Stanjek, and Vali 1990), as well as burning and the amount of certain iron oxides present in the soil (Evans and Heller 2003; Graham 1974).

Magnetometers

Magnetometers were first used on archaeological sites in England in the 1950s (Aitken 1961). It was not long before their use spread into other parts of Europe and over to the United States (Black and Johnston 1962; Herbich 2015). All magnetometers consist of the same general parts: (1) magnetic sensor(s) and (2) a control unit that runs the instrument, has a data display or settings interface, records data, and contains the batteries (Figure 1). There are several types of magnetic sensor, with unusual names such as proton free-precession, electron spin-resonance (Overhauser), and alkali-vapor (Optically Pumped) (Aspinall, Gaffney, and Schmidt 2008; Lowrie 2007). Perhaps the most common sensor type now used in archaeology

Figure 2 Illustration of the Earth's magnetic field (top) and the shapes and sizes of the magnetic fields of objects and archaeological features (bottom). Magnetometers, which are passive devices, can only detect subsurface features or objects that influence the magnetic field at the height of the instrument's sensors.

is the fluxgate sensor. Usually, two are paired together as a fluxgate gradiometer—the latter term indicates that this type of magnetometer records the difference between two sensors, which helps to filter out the daily fluctuations in the Earth’s magnetic field. Fluxgate sensors are highly sensitive to direction and must be aligned, in effect zeroed out, in all directions. Other magnetic sensor types, such as the commonly used Cesium Vapor type, detect the “total field” and are unaffected by the direction of survey.

As in most geophysical surveys, a magnetometer survey is conducted by moving an instrument back and forth across the site in parallel lines,

or transects, while the instrument records the magnetic values at a set rate. Four to 16 samples per meter along transects spaced 25–100 cm apart are common data densities. Most instruments simply record strings of numbers as the surveyor collects the data in a gridded pattern. Coordinates are assigned to each data value upon download (Figure 3, upper left). Modern magnetometer systems are now synched with precise global positioning systems (GPS) and each magnetic value is recorded with a geographic coordinate. Once they are downloaded, magnetic data often require processing to remove defects caused in data collection, such as striping due to running a

Figure 3 Magnetometry data visualization examples.

fluxgate gradiometer in two different directions. Interpolation can be used to boost data density, to a degree, and highlight smaller anomalies. Finally, image processing filters, such as the low pass filter, are used to minimize the small variations caused by subtle differences in the near-surface soil.

There are several ways to visualize magnetic data. A simple plot of the magnetic values at the locations where they were recorded is cumbersome, especially for large surveys (Figure 3, top left). Using contour lines to indicate trends across the data is useful in small survey areas, but this becomes overly complicated with large surveys and those with many anomalies. Even better is converting the values to cells, or rasters, that are colored according to the magnitude of the recorded magnetic value. Grayscale displays are most common for magnetic data; in the United States and other parts of the world, positive magnetic values are black and negative are white.

Magnetometry in archaeology

Magnetometry is the most popular of the geophysical survey techniques used in archaeology. It can be fast—GPS-enabled magnetometer arrays with probe spacings of 25 cm can cover over 12 hectares per day; smaller, single probe systems can cover half a hectare in a day. And whether small or large in extent, magnetometry surveys detect a wide range of feature types.

The effectiveness of magnetometry for finding features on archaeology sites depends on many factors, including soil type; the depth, size, and composition of the feature; and the magnetic data density. To be detected, a feature must stand out magnetically against the background magnetic levels of the site. Figure 4 exhibits a range of magnetic feature types. While there are many kinds of archaeological features, most can be characterized as cut or surface features. The most common are cut features, which are excavated down into the ground and include pits for burial,

Figure 4 An example of magnetic gradient anomaly types useful for archaeological sites in the northern hemisphere.

storage, and refuse disposal. In the northern hemisphere, these tend to appear in magnetic data as small positive anomalies (Figure 4). The accumulation of topsoil or magnetically enhanced archaeological midden in pits elevates their magnetic susceptibility. When pits are filled with burned sediment or certain types of rocks, they sometimes produce dipolar anomalies, similar to a weak bar magnetic buried on end. Iron objects and magnetic rocks are fairly distinctive in magnetic data as they produce dipoles, with positive and negative sides. Complex archaeological deposits, such as those containing a mix of iron objects, magnetic rocks, and burned sediment, can produce clusters of positive and negative anomalies. Linear features, such as foundation walls, earthen embankments, and filled ditches, are often the most readily identified features when detected. Though some interpretations of magnetometry data are obvious, verification through coring or excavation (often referred to as “ground-truthing”) or survey with additional instrument types can improve interpretations.

Marine Excavation

GREGORY D. COOK

University of West Florida, USA

“Marine excavation” as a topic can have a variety of meanings, and obviously the excavation of an area of seafloor can have a multitude of purposes ranging from archaeological investigation to the dredging of shipping channels, dock, pier, and bridge construction, and other types of applications. Even within the topic of scientific diving, marine excavation is conducted in a number of contexts. These can include excavation of shipwrecks, aircraft, submerged archaeological sites, sediment sampling for biological/environmental analyses, or dry-land excavations on wrecked or abandoned vessels that now lie under land (for an extreme version of this latter context, refer to the steamboat *Arabia* in Hawley 2005). For the purposes of this entry, marine excavation will refer to the excavation of submerged archaeological sites in an underwater context, as land excavations on non-wet shipwreck sites utilize rather standard methods of terrestrial excavation.

Before delving deeper into the topic, some consideration must be made as to the reasons for excavation, as this is a destructive process. Even if removal of sediments is not inherently harmful to the specific site being studied, removal of artifacts, features, and other aspects of the material culture of the site precludes these items from ever being returned exactly in their original context. Generally, broad-scale excavation only is considered justified after the creation of a research design in which careful consideration of survey, testing, and excavation strategies is outlined. A valid research design could include a literature search for previous studies related to the site, a clear statement of project objectives and methods to be used for each phase of the project, sources of funding, the timetable for fieldwork, analysis, conservation, and publication, considerations of crew requirements and support, and a safety plan (specifically a dive safety plan).

Doing scientific fieldwork underwater presents many complications and challenges, and safety should remain paramount throughout the project. The underwater environment must be an uppermost factor in planning the research project, as it affects nearly all aspects of the fieldwork. How deep is the site (how much bottom time is each dive team going to have on the site)? Are there tides/currents that will affect fieldwork? What is the water temperature? Will divers need wet suits or dry suits, or additional training on the specific techniques employed in working on the site? How much visibility is there on the site? Is there dangerous marine life? Where is the nearest recompression chamber? These are just some of the basic questions that should be considered when planning underwater fieldwork.

No underwater archaeological research project should move forward without a coherent plan and funds for conservation of the finds that will be generated from the excavation, as well as storage space and a collections management plan for any artifact collections that may be generated from the project (for project planning considerations see UNESCO 2001, Convention on the Protection of the Underwater Cultural Heritage, rules 9 and 10). Due to the complexity and cost of broad-scale maritime archaeological excavations, there is a growing trend toward noninvasive techniques and the principle of in-situ preservation as the preferred approach to studying submerged sites as finite, nonrenewable resources (see Bowens 2009, 135–136). When, however, the above topics have been considered and a proper research program has been designed, and archaeological excavation is the only way to move forward, there are various aspects of marine archaeological excavation at our disposal.

As the specialized field of maritime archaeology developed, a variety of methods have been devised for removal of sediment from submerged sites. These range from low-tech options such as hand fanning, manual digging using specialized hand tools, to mid-level techniques including water induction dredges, air lifts, and water jets, to larger, industrial-level systems such as dredge

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0359

barges and other types of heavy machinery. It is impossible to summarize the range of approaches and techniques that have been used over the years and during countless projects for the removal of sediments from underwater sites, but several standard methods have been utilized in multiple contexts and will be presented here. During this discussion, the author may describe specific techniques or examples utilized by scientific divers at the University of West Florida (UWF), but it should be remembered that there are usually several good approaches to site excavation, and there may be other methods that work just as well.

Of the various “low-tech” methods, the human hand can be considered the most basic approach to removal of sediments underwater (Muckelroy 1978, 24–36). Whether hoping to gain a glimpse of the source of a remote sensing anomaly, or “dusting” the surfaces of pre-exposed timbers to expose details such as wood grain or fastener patterns, hand-fanning can be an effective way to move small amounts of sediments in a careful, controlled manner. This method is free, always available, and in low visibility our divers often take off one glove, or utilize fingerless gloves, to allow greater sensitivity when going through the soil matrix. Using your hands to direct sediments toward a dredge or other sediment removal system can be very effective as well, and if, for example, the hose of a water induction dredge could be considered the “shovel,” hand-fanning could be considered the “trowel,” allowing the skilful diver to remove individual grains of sand if need be while keeping the dredge lifted away from the feature being excavated. Along with hand-fanning, any number of extraneous tools have proven their worth during underwater excavation: some that have been useful to us at UWF include trowels (the same kinds used on terrestrial sites), brushes, spoons, dental tools, plastic/bone folder tools, plastic spatulas, dust pans, cups, and buckets. Small-mesh bags with secure drawstrings and a clip to allow you to secure these tools to your dive gear are indispensable for managing these implements while diving. In short, when faced with a particular problem in low-tech sediment removal, a trip to the local hardware store can lead to creative solutions for marine excavation.

If hand-fanning is not sufficient for adequate excavation of a site, then various other methods of mechanical removal of sediments have been developed and adapted for maritime archaeology. Two common techniques involve incorporating suction dredges to remove sediments to screening stations, exhaust bags, or disposal/spoil areas away from the site. On sites with sufficient depth, the use of airlifts has proven beneficial and not overly complicated. The principle here is to inject air from a surface compressor near the bottom of the lift (a tube or pipe) in a controlled manner, which will then force the discharge end of the lift in a close to vertical orientation. As the air injected into the bottom of the lift rises, decreasing pressure causes it to expand, creating suction at the bottom end of the lift. There are numerous variables involved in making any mechanical suction system work sufficiently, such as tube/pipe diameter, output of air compressor, and number of airlifts used. Some airlifts need to be anchored at their suction end due to buoyancy generated through the air being injected into the lift. A crucial consideration with airlifts is water depth: typically they work best when there is at least one-half to one atmosphere of pressure difference between the bottom sediments being excavated and the surface (around 5–10 m), though they have been used successfully in shallower waters with less efficiency (Green 2004, 252–256). In significantly deeper waters, a compressor with enough force to push air to the bottom of the pipe/tube is required, which can affect the project budget as these tend to be expensive, and also requires a sizeable research vessel or diving platform for operation. Another factor to consider is where the spoil exiting the exhaust end of the lift is being directed to: If collection and screening of spoil is desired in the case of small finds being excavated in the dredge spoil, then a screen or similar means for sifting through the spoil can be fitted to the end of the lift. Alternatively, the airlift can be arranged to exhaust spoil to a surface screen or collection point. The pipe/tube should be situated so that material exiting the airlift can flow down-current if possible, to avoid dumping excavated material back on site and affecting diver visibility.

A second means of creating a suction dredge involves pumping water, rather than air, through hoses to a suction nozzle, commonly known

as a water induction dredge. As with airlifts, there are many variations in this design, and some are commercially available through gold dredging suppliers and other industrial sources. The basic operation requires a water pump, and for shallow water excavation UWF archaeologists use a 5.5-horsepower pump with 7.6-cm (3-inch) hoses/fittings. A semi-rigid intake hose allows water to be sucked into the pump, which is then transferred through the pump's outflow to a collapsible hose that extends to the suction nozzle, which typically lies on the seafloor near the site being excavated. The hose attaches to the nozzle at an angle, so that the force of the water entering the nozzle is directed to the exhaust end of the system. This creates suction at the open end of the nozzle, which is often fitted with a flexible hose that divers can manipulate during excavation. This system has several advantages: It is relatively cheap to design (UWF archaeologists construct their dredges with PVC pipe) and can be used in shallower water than airlifts; the water pumps are typically cheaper and lighter than compressors, and can often be deployed on small craft; and the fact that the dredge lies on the seafloor reduces turbidity (the amount of material being introduced into the water column), which can affect the environmental impact of the operation, and may be an issue depending on permits and agencies overseeing the research project.

Methods mentioned above have successfully been implemented on remotely operated vehicles (see Søreide 2011). Other, more industrial means of sediment removal exist, including very powerful airlift and induction dredge designs implemented from barges, cranes, or other large support vessels, or removal of sediments by construction equipment such as clam-shell grabbers and other machines. At this scale, scientists usually work closely with professional construction managers or engineers in order to conduct the project, and specific situations vary immensely. At the very least, however, consideration and careful planning should go into issues such as safety and the proveniencing of artifacts uncovered during such operations, as the archaeological context of the site remains paramount.

Other considerations with using any kind of mechanical excavation equipment include safe handling by divers. At UWF, new scientific

divers go through a week of training prior to any fieldwork, where they review all of their open-water diving skills, as well as learn how to set up dredges and move heavy equipment, first on land, then underwater in the pool, and finally in the murkier waters of Pensacola Bay, all under supervised, controlled conditions. This type of specialized diving goes beyond what is taught in most basic open-water SCUBA classes, and every project should go over protocols and how to operate the machinery specific to that project, regardless of how experienced the field crew may be. Potential hazards from using the kinds of equipment mentioned above might include: inadvertently sucking up part of the diver's equipment into the dredge or injuring one's hand in the dredge (a shut-off valve or system for shutting off the dredge from the surface should be implemented); uncontrolled ascents when air is introduced into a system component such as an airlift; uncontrolled descents when passing off heavy excavation gear to divers in the water who are unprepared for the added weight to their buoyancy; and low visibility conditions, when dredging disturbs bottom sediments and divers can experience "black out" conditions, to name just a few.

Provenience is a final issue that should be mentioned. Establishing artifact context in three dimensions, or "XYZ" format, is a basic requirement for archaeological fieldwork. This can be done in a variety of ways, but often a grid system is established on the seafloor prior to excavation, and any finds, features, or hull remains are mapped in relation to this grid system (Green 2004, 237–240). This is also effective in proveniencing any small artifacts inadvertently sucked up the dredge during periods of low visibility. Regardless of how careful the diver is, small finds such as bones, beads, and fasteners may be removed by the dredge on accident. Having a means of gathering dredge spoil (we use double-mesh bags attached to the exhaust of our dredges) allows for the collection of this material, and utilizing a grid system provides locational data for where the objects came from on the site. UWF divers utilize a rigid aluminum grid, composed of 1-m lengths connected to six-sided "stars," or corner joints that allow the 1-m lengths of aluminum shafts to form a $1 \times 1 \text{ m}^2$, with a vertical shaft allowing longer lengths if needed

for vertical support. These horizontal and vertical shafts then can be secured with zip ties or thumb-screws. The flexibility of this system is that it can be created on an as-needed basis, starting with a 1×1 or 2×2 , and then can be expanded by dive teams adding more material to the grid system. Plastic tags marked with unit designations are affixed to the northeast corner (this is arbitrary, but should be standardized as to the best location for the specific site), so that even in low visibility divers can easily navigate to the current unit being excavated. There are many other ways of establishing provenience, so this should be a clear part of the research design and considered of paramount importance for excavation activities.

Mobile Geographic Information Systems (MGIS)

SCOTT A. GUNN

University of New Mexico, USA

Mobile geographic information systems (MGIS) are a framework that combines spatial and non-spatial data within a mobile platform for field data collection and mapping. MGIS tools have been fervently adopted by many field archaeologists in recent decades and have become an essential component in the process of recording cultural resources in government, academic, and cultural resource management (CRM) settings. Due to the rapid pace of development and improvements in mobile data collection devices, batteries, and global positioning system (GPS) technology, archaeologists now have an abundance of MGIS hardware and software to select from and have the ability to tailor these solutions to meet ever-changing project requirements. As more and more components of archaeological fieldwork move to a born-digital form, MGIS systems play an essential role in linking spatial data within archaeological contexts to nonspatial data, including photographs, field notes, regulatory forms or paperwork, and other textual data. Linked and combined together, these datasets can quickly and efficiently aid and inform archaeological analysis and interpretation without the laborious, and sometimes error prone, digitization and transcription efforts required in the past.

MGIS frameworks developed concurrently with the widespread use of desktop computer-based GIS in archaeology, as GIS databases became the de-facto digital data warehouse for spatial archaeological data. Early MGIS platforms required large data collection hardware, including laptop, mobile, or handheld personal computers (PCs) linked to external GPS

receivers. These initial hardware and software systems, however, could be large and cumbersome, and were therefore slow to be adopted in most archaeological fieldwork situations (Wallrodt 2016).

As a result of rapid improvements in mobile computing, more recent MGIS hardware is smaller and more portable, and can run for hours, or even days, on a single battery charge. These devices, including cellular phones, tablets, and laptops, can include large sunlight-readable touch screens and are often ruggedized and weatherproof in some form. Newer devices include integrated mapping-grade GPS receivers, or can be linked to any number of high-accuracy external GPS systems via cables or Bluetooth. Additionally, through post-processing or via mobile communication links to virtual reference stations (VRS), high accuracy differential GPS (DGPS) systems (see GPS (GLOBAL POSITIONING SYSTEM)) may provide centimeter or better spatial accuracy to any number of MGIS hardware and software solutions.

In combination with mobile wireless, or cellular connectivity, many MGIS hardware systems can be linked back to the laboratory or office for a real-time review of archaeological field crew progress. Archaeological data can be immediately stored in desktop or web-based GIS databases for analysis, interpretation, and reporting before fieldwork has been completed. However, given the remote nature of some archaeological fieldwork, real-time updates may not be possible or could be subject to expensive mobile data plans in many regions of the world. In the absence of wireless data transfers, physical backups via external storage cards should be considered to prevent data loss. Further, remote field conditions may require additional batteries or other means of charging MGIS hardware. These power sources may include solar charging systems, external battery banks, or portable gas-powered generators.

A variety of proprietary MGIS hardware systems are available to archaeologists, manufactured by large geospatial companies such

as Trimble, Leica, Garmin, and CHC. These all-inclusive devices include internal GPS receivers and, while some systems require post-processing to improve locational accuracy, many deliver real-time sub-meter or better solutions with satellite-based augmentation systems (SBAS) or VRS. A limiting factor to these proprietary systems is that the archaeologist is often tied to manufacturer-specific software such as TerraSync, ArcPad, or SurvCE. Using this software, the archaeologist may have very little control over data dictionary design, data collection workflow, and interoperability. These software programs may also require specialized vendor-provided training and expensive maintenance contracts. However, a large number of MGIS hardware devices are now available that are based on Android-based operating systems, or can pair via Bluetooth with any number of Android or iOS tablets or mobile phones. This advancement opens up the MGIS data collection workflow and allows the user to use any number of open source, or custom designed and developed, data collection applications.

Various MGIS software solutions exist for archaeological fieldwork applications. Commercial, and often proprietary, software includes Esri ArcPad, ArcGIS Collector, Trimble TerraSync, Carlson SurvCE, Leica MobileMatriX, Fulcrum, and Filemaker Pro. Depending on the project's chosen hardware platform, free and open source software is also available for MGIS data collection, including Open Data Kit (ODK), SurveyCTO, QGIS Mobile, and FAIMS Mobile. Installed on Android-based systems, these software applications can easily be paired with high-accuracy Bluetooth GPS receivers from a variety of manufacturers with a range of advertised accuracies, including the Bad Elf (1–3 m), Trimble R1 (60 cm), SXBlue III (1 cm), and EOS Arrow (1 cm).

Nearly all of these software solutions, both commercial and free or open source, allow the field archaeologist to load predefined data dictionaries or database schemas, project areas, recent satellite imagery, georeferenced historical imagery, or custom basemaps prior to the start of MGIS data collection. In addition to acting as a basic navigational aid, these datasets allow the archaeologist to make better informed decisions when undertaking new survey or excavation

projects. In some cases, paper forms can be digitized prior to fieldwork and these attributes can be linked to point, line, and polygon GIS data collected in the field. Additionally, depending on the nature of the project, the process of preloading spatial information into MGIS software can allow the archaeologist to ground-truth and record archaeological features, or other areas of interest, identified through imagery or model-based analysis in the laboratory (Tripcevich 2004). Once in the field, many devices allow the user to sketch archaeological features, profiles, and other objects of interest with a digital pen or stylus that can be used in subsequent analysis and reporting. All software generally includes the ability to view data already collected on a project, and make changes to extant data or append additional data before fieldwork concludes.

With a carefully designed data collection strategy in place, digitized field forms can be readily integrated and combined with MGIS spatial data after fieldwork. This provides considerable time savings over past practices that required the often tedious process of transcribing field notes and other data entry work. Additionally, born-digital data reduces transcription errors, and improves data reliability, consistency, and interoperability. Collected within a holistic MGIS framework, data that once may have existed in isolation, such as photographs, data tables, and field notes, can provide an interactive reference for analysis, interpretation, and reporting. In this form, the process of data sharing is greatly simplified and collaboration becomes a more fluid process. Further, within a relational database, all field data, form data and attributes, locational data, and photos can be linked for use within a desktop GIS application (ArcGIS, QGIS) or hosted on a web-accessible database for presentation on any number of web-based mapping applications.

To date, MGIS has been adopted widely by archaeologists in pedestrian survey, reconnaissance, and excavation contexts around the globe (de Roo, Bourgeois, and De Maeyer 2013). In excavation projects, MGIS devices have been used for artifact cataloging and tracking when combined with portable, battery-powered barcode printers (Parker and Eldridge 2014). Custom software and database applications have been developed for MGIS in archaeology, including

FAIMS, ArcheoLINK, and the Archaeological Recording Kit (ARK). These applications provide a framework for collecting, storing, and reviewing both spatial and textual archaeological data and, after undergoing training in software development, the archaeologist can often customize these applications to meet any number of research requirements.

MGIS will remain even more relevant moving forward as archaeological fieldwork continues to require the collection of more and more spatial data and other digital information. Digital data collection may become even more critical within regulatory environments that emphasize nondestructive and noninvasive archaeological investigations. However, some archaeologists may encounter a number of problems when striving to meet these challenges. As more and more research designs call for the collection of very large spatial datasets, including those acquired through light detection and ranging (LiDAR) (see TERRESTRIAL LIDAR) or unmanned aerial vehicles (UAVs) (see DRONES), or generated through photogrammetric processing (see PHOTOGRAMMETRY AND STEREOPHOTOGRAMMETRY) in addition to that of traditional field recording, data storage and management can become problematic. Furthermore, without careful planning, MGIS datasets can become isolated from their larger context and may remain unavailable for sharing and integration (McCoy and Ladefoged 2009). To avoid this, prudent consideration should be given to data storage, database management, and database design before undertaking such projects. These approaches require a well-researched, holistic approach to data collection with a solid, yet flexible and expandable, database design. Ample resources need to be provided for data storage plans, backups need to be performed regularly, and, to prevent unintended data manipulation or destruction, data versioning should be implemented when possible. Additionally, archaeologists, particularly those with supervisory roles, need to be provided with professional development opportunities and any other necessary training that teaches appropriate MGIS data collection practices.

Future MGIS systems may allow for the ability to perform spatial analysis, such as kriging or other density analyses, while in the field to identify artifact or feature concentrations that

inform subsequent testing, sampling, or excavation. Additionally, with some training, the development of MGIS systems can provide an exciting starting point for the sharing of custom archaeological applications, digitized field forms, and other collaborative products through the use of source code sharing websites such as Github. Given further improvements in hardware and software development, research and collaboration, and real-world testing and implementation, MGIS will continue to be a highly relevant tool for documenting and understanding cultural resources.

Photogrammetry and Stereophotogrammetry

MATTHEW MAGNANI

Harvard University, USA

MATTHEW DOUGLASS

University of Nebraska–Lincoln, USA

Historical perspectives on photogrammetry and stereophotogrammetry

Closely following the invention of photography in the mid-1800s, stereophotogrammetry emerged as the science of extracting metric data from pairs of still photographs. Although commonly employed and developed by governments for civil and military purposes (often using aerial photographs), it was not until the 1970s that archaeological publications employing photogrammetry became routine. Early applications in archaeology often featured specialized pairs of fixed-base cameras with precise calibration to take stereopairs of photographs, although individual cameras could also be moved to achieve similar ends.

Early applications of stereophotogrammetry both facilitated the display of archaeological findings and aided in analysis. Subjects of study ranged in scale from engravings to monument complexes, and allowed linear and volumetric measurements to be made. Despite its acknowledged potential, in its earlier form the technology did not see widespread use by archaeologists; stereoscopic equipment was expensive and highly specialized, costing over six figures in the 1970s, and required a skilled operator. Some of these concerns were mitigated with increasing use of computers in analysis, although photogrammetry remained a relatively specialized tool into the early 2000s. While originally clumsy and inaccessible, early developments established both the conceptual and technological foundation for modern photogrammetry to progress.

Contemporary photogrammetry

More recently, a number of user-friendly software packages have been developed to process photogrammetric models from multiple source images (e.g., Autodesk's 123D Catch, Visual SFM, or Agisoft PhotoScan) in conjunction with almost any digital camera and computer workstation. Through application of computer-vision algorithms including structure from motion, or SfM, like points within a series of overlapping photographs are used to generate three-dimensional datasets and orient camera positions (see Green, Bevan and Shapland 2014 for a discussion of SfM). In addition to producing qualitatively and quantitatively accurate model surfaces, photogrammetric techniques facilitate the production of detailed, photo-realistic textures that surpass in quality the other modeling options. While technically complicated, in contrast to early iterations of the process, most software employed today simplifies the workflow in data processing for users, making it one of the best options available for archaeologists interested in producing three-dimensional datasets. The resulting models are easily disseminated via the Internet to facilitate remote research and outreach.

Compared with current applications of laser scanning (see LASER SCANNING), structured light scanning (see STRUCTURED LIGHT SCANNING), lidar (see TERRESTRIAL LIDAR, AIRBORNE LASER SCANNING AND LIDAR), or CT scanning (see COMPUTED TOMOGRAPHY), photogrammetry confers a number of benefits. Unlike those technologies, which require expensive hardware, software, and specialized technicians, photogrammetric setups cost only as much as a digital camera, and data can be collected by anyone who can take photographs. Open-source software for model building and free web platforms for display further add to the affordability and accessibility of photogrammetry to a wide range of users. Whereas these other technologies require a dedicated and stable power source and are comparatively difficult, if not impossible, to bring to most archaeological field sites, no such issues are encountered with photogrammetry. Digital cameras are easily trans-

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0451

ported, charged, and used under most field conditions, and basic modeling for quality control can be completed in the field using laptops. Additionally, data collection can be significantly less time intensive compared with the other listed methods.

The strengths of photogrammetry also confer weaknesses that have been recognized for some time. Issues with operator skill and variation in model quality are more acute in photogrammetry than other technologies that have less mutable workflows and carry a higher price. Depending on the data-collection practices followed, this means that photogrammetric models of the same subject may vary considerably more than those made using other modeling options. Despite this, recent attempts to standardize workflows and suggest best practices have eliminated some of these issues, and it is expected that, with time, photogrammetrical routines will continue to be refined.

Photogrammetry has been utilized to create datasets from a number of different vantage points and scales. Across these scales, comprehensive best practices have been suggested to enable better accuracy and repeatability (e.g., Porter, Roussel, and Soressi 2016). Most frequently, the models are used in well-established forms of analysis already conducted by archaeologists: to take basic linear measurements, calculate volume, or to visualize and record changes in excavation surfaces through time, for example. These applications have been employed at a number of different scales with different image acquisition and modeling routines: from small artifacts photographed on turntables, to entire landscapes captured by unmanned aerial vehicles. In addition to using photographs taken explicitly to produce photogrammetric models, researchers have also used photographs collected historically, or through crowdsourcing, to generate 3D models of heritage objects (see *DESIGNING AND CO-CREATING HERITAGE*) that has been destroyed due to natural disaster or conflict (Grün, Remondino, and Zhang 2004).

Object-based photogrammetry

Archaeologists have modeled individual objects, ranging from stone tools and ceramics to larger

stone carvings. Working with smaller subjects gives photographers the option to control their data-collection parameters, including light and camera settings, which has been shown to impact qualitative results (Magnani, Douglass, and Porter 2016). In cases where objects are small and appropriate materials are available, placing the object on a turntable permits photographers to leave their cameras in fixed positions while the object is rotated. This permits more stable, regularized photographs to be taken (Porter et al. 2016). In most cases and with larger objects, however, a camera's position is physically moved around the artifact. The method is particularly suitable for gathering field data in cases where time is limited and artifacts cannot be collected. For the smallest subjects, studies have indicated no significant differences in measurements between traditional caliper measurements and photogrammetric models, and model quality is noted to produce textures of sufficient detail to permit the observation of important elements of artifacts (e.g., raw material, flake scar direction in the case of stone tools). Other works have demonstrated the utility of the technology to model surface modifications on individual objects, like cut marks made with different tools on bone (Maté-González et al. 2016). Basic linear, volumetric, and geometric morphometric (see *GEOMETRIC MORPHOMETRICS*) measurements may also be taken using photogrammetrically-derived three-dimensional models.

Ground-based photogrammetry

Ground-based features and excavation surfaces have also been modeled. Unlike working with smaller objects that are frequently photographed indoors, working with larger, often outdoor subjects affords photographers less control over environmental parameters like lighting. However, the benefits of using such recording techniques have been emphasized in survey contexts where data collection for photogrammetry was faster to collect than line drawings for hearths, wells, and other features (Douglass, Lin, and Chodoronek 2015), and richer than data collected by total station measurements (see *TOTAL STATION*) for earthworks (Magnani and Schroder 2015).

Specific photogrammetry routines have been reported as less precise than total station measurements, although they can be used to visualize individual artifacts in situ. When conducted at regular intervals, models provide a detailed record of excavation progress and site stratigraphy. In many cases, ground control points (GCPs, or identifiable marks in known locations) are recommended to ensure accuracy, tethered to known coordinates which permits the orientation of the model in space (Green et al. 2014). For features, accuracy to approximately one centimeter is achievable. While most research has dealt with terrestrial subjects, general principles applied on land are also appropriate for use underwater, so long as distortion from water is taken into consideration.

Aerial photogrammetry

Photographs taken from airplanes, unmanned drones, kites, balloons, or even large camera booms have been used to generate topographical maps of landscapes, or other larger monumental archaeological features. Aerial photogrammetry allows for similar analyses to ground-based and object-based photogrammetry on a larger scale (for example, in showing the change in volume of larger excavation surfaces through time). Aerial photogrammetry provides an affordable alternative to lidar systems in particular, yet unlike other technologies, provides detailed photographic textures. Compared with measurements taken using total stations, the method provides a significantly faster way to generate elevation maps. Studies have emphasized the accuracy of the digital elevation models yielded from georeferenced aerial photography, between 0.14 and 0.31 meters (95% confidence interval), and models have even been generated using old pairs of stereophotographs from aerial surveys (Verhoeven, Taelman, and Vermeulen 2012).

Photogrammetry looking forward

In just the last decade, photogrammetry has become widely accessible to archaeologists. In this short time, the technology has already proven

itself as a useful and most accessible tool for those interested in creating 3D models ranging in size from individual objects to larger features and structures. As user-defined photogrammetric workflows and the software packages used to process photographs become better refined, the quality of models generated for archaeological analyses will continue to increase. Beyond improving archaeological analyses, photogrammetry has begun to show promise as a tool to communicate and engage with broader publics (Douglass et al. 2017), through a general democratization of access to archaeological subjects, and even by facilitating participation in projects through crowd-sourcing photos of lost heritage. However, while publications abound related to the use and development of photogrammetric techniques, the technology has yet to realize its potential in the hands of archaeologists; thus far, most publications have focused on proofs of concept and emphasized the use of the new technology to take traditional archaeological measurements more efficiently. Through future innovation in application, the technology will begin to reach its full potential.

Portable X-Ray Fluorescence Spectrometry (pXRF)

ROBERT H. TYKOT
University of South Florida, USA

Introduction

Many methods of elemental analysis have been used on archaeological materials to address their overall composition or specific elements to identify the source of their geological components. Early in this millennium, however, non-destructive portable X-ray fluorescence (pXRF) spectrometers were commercially developed, allowing analyses to be performed within museums around the world, on virtually any size of artifact (Morgenstein and Redmount 2005; Cecil et al. 2007; Craig et al. 2007) (Figure 1). Early concerns about data calibration have largely been dealt with, while surface analysis of heterogeneous materials will always be limited to semi-quantitative results. Overall, the use of pXRF has led to large-scale studies of obsidian, ceramics, metal, and other materials, as well as studies on specific objects where elemental analysis simply was not previously possible (Tykot 2016). Just like any other analytical instrument, a pXRF user needs appropriate training and understanding of its principles, advantages, and limitations (Liritzis and Zacharias 2013; Shugar 2013).

Principles of X-ray fluorescence and pXRF

Energy dispersive X-ray fluorescence (ED-XRF) spectrometers measure the energy level and intensity of secondary (fluorescent radiation) X-rays produced by primary X-rays striking the sample and creating vacancies in an inner shell of the atoms, which are then filled by lower-energy electrons from an outer shell. The

energy difference between specific shells is fixed but varies between elements, so that secondary X-rays have a characteristic transition energy and thus may be attributed to specific elements. The strongest X-ray intensity results from an L-shell electron replacing a K-shell vacancy is called $K\alpha$, while an M-shell electron replacing a K-shell vacancy is called $K\beta$. The replacement of L-shell vacancies by M-shell electrons is called $L\alpha$ and by N-shell electrons, $L\beta$.

For both portable and regular ED-XRF spectrometers, energy level and intensity are measured by a detector, with the raw data calibrated using standards and appropriate software. The standards used for X-ray analyses must be of similar bulk material to the objects being analyzed, since the ability of the secondary X-rays to reach the detector is affected by the composition of the matrix. Calibration has been widely established for silicate materials including obsidian and many ceramics, but to a lesser degree for metals and other materials. Calibrated results are always necessary for comparing data from different analytical instruments (e.g., Goodale et al. 2012; Williams, Dussubieux, and Nash 2012).

The fundamental difference between regular and portable XRF instruments is the exterior location of the sample. But while the pXRF does not require destructive sampling of larger objects, they are not within a vacuum chamber, which is necessary for the detection of X-rays from lower atomic number (Z) elements that otherwise are absorbed in air. This is partly resolved when a vacuum is created within the pXRF (using a portable generator connected by a small tube) and the sample is flat, so that there is no air space in between the sample and the instrument window. The precision of measurements on elements such as Mg, Al, Si, and P, however, is not nearly as good as for higher Z elements, and elements below Na are not detectable at all. The other major difference with pXRF is its detection limits, as much as an order of magnitude less than for ED-XRF, and therefore providing fewer trace elements that may be used in archaeological sourcing studies. For the pXRF, filters have been designed for different materials to reduce the

background signal and maximize detection limits and precision.

Many archaeological materials may be heterogeneous, whether naturally (e.g., lithics), as a result of their production (e.g., ceramics), or due to degradation and contamination (e.g., metals). Pottery may be a combination of clay and temper, as well as having slip or paint on the surface, and copper-based metals may have pooling of lead and other elements, as well as corrosion on the surface. Care must be taken with what spots are chosen for analysis; recently broken (or freshly cut) edges of pottery may be better than the inner or outer surfaces. Using a pXRF, however, always allows multiple spot analyses so that trends and directions of surface contamination may be observed and incorporated into selection of additional analyses and interpretation of results.

Separate from issues of heterogeneity in archaeological samples is the precision of the pXRF. One study involved 25 separate analyses

on the same spot, for five different pottery sherds, as well as analysis of multiple spots on each sherd. This study showed that the precision was similar to regular XRF instruments—much better than the actual variation within the ceramics—and only a tiny fraction of the differences observed between ceramic source groups.

Multiple brands and models of pXRF instruments are available, with the same basic analytical principles, but different features and amenities. These include the sensitivity of the detector, and therefore the analytical time necessary; the size of the beam, and thus the area being analyzed; and the ability to adjust settings of voltage, amperage, and filter types to maximize results for different materials. In the examples presented here, two different pXRF models were used, with different filters when analyzing major elements in metals, or trace elements in lithics and ceramics. For major elements the analysis time selected ranged from 30–60 seconds, while for trace elements from 120–300 seconds. For many obsidian

artifact studies, an even shorter time is possible given the known variance between possible sources in particular regions, allowing analyses of more than 200 artifacts in just one day.

Archaeological applications

Obsidian

Given the homogeneity of obsidian, and insignificant changes between raw material and artifact, it is perhaps the most appropriate and easiest material to analyze by pXRF, with many studies published around the world. More than 7,000 obsidian artifacts from archaeological sites in the central Mediterranean have been analyzed to determine their geological source and to reconstruct trade. Following a detailed survey and collection of geological source samples on the Italian islands of Lipari, Palmarola, Pantelleria, and Sardinia, analyses by pXRF demonstrate that each may be distinguished from each other as well as from Melos in the Aegean and the Carpathian sources in the Balkans by just a few trace elements (Rb, Sr, Y, Zr, Nb).

The pXRF is even capable of distinguishing subsources for each island, with studies showing geographical and chronological differences in their relative usage. It is the attribution of obsidian artifacts to specific geological subsources that enables better understanding and interpretation of material selection, trade routes, and the socioeconomic systems in which they were embedded.

Ceramics

Ceramics may be heterogeneous due to how the clay is prepared and whether temper is added, while the surface may have slip, paint, or glaze, which may be an obstacle in doing non-destructive pXRF analysis. There are many potential clay sources that may have been used, with potential access to many points along rivers, and rarely a database with which to compare results on sherds. Instead, pottery “sources” are defined archaeologically with finds of production sites (e.g., kilns, wasters) and large assemblages of everyday wares. Using the pXRF allows analyses

of enough sherds to establish a local group, even if coming from multiple outcrops in the area and of different clay types, which may be further distinguished by analysis of more trace elements using INAA or ICP. Conducting such studies on multiple sites in a region provides information on possible locations of outliers from one site.

A number of ceramic studies using pXRF analyses have been published, several directly focused on the methodology and comparison with other analytical instruments, and others on particular research questions in many parts of the world. One was on prehistoric southeastern US ceramics, with multiple spot analyses of more than 500 ceramic artifacts from eight sites in northwest Florida. These included clay balls known as Poverty Point Objects from the Choctawhatchee Bay area, Tick Island in northeastern Florida, and the site of Poverty Point in Louisiana. Principal components analysis using Rb, Sr, Y, Zr, and Nb shows that several fall well outside the Apalachicola River group, and match with those from Poverty Point. These results support the hypothesis of small-scale, long-distance exchange between northern Florida and Louisiana.

Metals

The main use of elemental analysis on metal artifacts is for determining bulk element composition. The results for large numbers of copper-based as well as gold, silver, and lead objects may be used for assessing changes in production technology, access to tin and other metals, consistency in alloying different materials (e.g., tools, weapons, jewelry), and practices of recycling. Analyses also provide proper identification and description for museum exhibits and catalogues, and for many acquired museum collections, identifying some which are not authentic.

Conducting non-destructive analysis on the surface, however, raises potential problems due to degradation and/or contamination, as well as conservation practices that may have altered the composition. Analysis of multiple spots can quickly reveal significant variability in composition, which is not characteristic of a cast object, and perhaps a small area may be cleaned for reanalysis.

In the Orlando Museum, all but one of the “gold” objects are in fact tumbaga alloys, with high percentages of silver and copper (Figure 1). Other objects are labeled as “copper” or “metal”, with analyses revealing many as arsenical copper and just a few as bronze. One artifact, a knife, has too much Zn to be authentic. In the Tampa Museum, all objects were labelled as “bronze” or “silver”. An “Etruscan” object with Zn must be a fake since brass was not produced at that time. Four of the “silver” coins were mostly nickel, therefore also fake.

At the Roman site of Thamusida in Morocco, excavations revealed military equipment, including buckles, scabbards and horse harness fittings, and military diplomas. Dating to the early second to the third century CE, there were a great variety of copper-based alloys, with Sn and Zn in nearly all, many with Pb, and a surprising number with As and/or Ag. The compositions do not appear to be related to the social or functional purpose of the objects, but rather to the availability of raw and scrap materials.

Paintings

Analysis by pXRF of selected spots on painted surfaces produces results from varying depths based on thickness and composition, but cannot detect organic paints, and cannot distinguish colors based on their oxidation states. At the neolithic Genovese Cave on the island of Levanzo (Sicily), the pXRF was used to identify the kind of paint based on differences in element concentrations when compared with unpainted spots. The black figures had higher iron concentrations, sometimes also manganese, and others had the same composition as the adjacent unpainted rock surface, suggesting the use of charcoal. Red figures were always of iron (ochre), while white paint was high in calcium.

For later time periods, when many kinds of paints were used, just having elemental results may be limiting. Nevertheless, Cu peaks confirm what is thought for greenish colors, and gold-looking paint is usually pure gold. Red, however, may come from Fe-containing minerals or from the mercury (Hg) in cinnabar, as has been found in museums in Norway and in Sicily. Some Hg also was detected in non-red areas, suggesting

cinnabar was used in an earlier version now painted over. Tyrian red (or royal purple) is made from murex shellfish, and its use in paintings may be confirmed by a high bromine (Br) peak.

Bone

Measuring elemental concentrations in bone or teeth is well established for studying dietary practices (Ca, Sr, Ba) as well as potential consumption of poisons (Pb, As), and can complement isotopic analyses. The ratios Sr/Ca and Ba/Ca decrease with trophic level, so are especially indicative of the consumption of aquatic resources. While other studies are done on interior samples that are ashed, analysis by pXRF of a well-cleaned surface may also be successful. Bones from 67 individuals from four sites in Florida were analyzed. Those from the inland site of Belle Glade had the highest ratios; Miami One on the Atlantic coast had lower values; and Horr’s Island and Weeden Island on the Gulf coast had the lowest. The tight clustering of the Horr’s Island and Weeden Island individuals supports the premise that the results are reliable and not significantly altered by contamination and/or decay. The results are also consistent with greater and more regular accessibility of marine foods on the shallower Gulf side, as confirmed by stable carbon and nitrogen isotope analyses.

Radar

KRISTIN N. SAFI

University of Tennessee, Knoxville, USA

This discussion of radio detection and ranging (RADAR) focuses on two categories that are most applicable to archaeological research: SYNTHETIC APERTURE RADAR and GROUND-PENETRATING RADAR. RADAR is an active remote-sensing (see AIRBORNE REMOTE SENSING) technique where pulses of a generated energy signal (a radio wave) are sent out through a transmitting antenna, and the direction and quantity of backscattered or reflected energy are recorded by a receiving antenna (Conyers 2013). Both SAR and GPR operate in the microwave portion of the electromagnetic (EM) spectrum. In GPR, the depth of ground penetration is linked to the physical size of the antenna and the oscillating frequency of the transmitted wave. In SAR, finer pixel resolution is achieved by approaching a target from multiple viewing angles and processing the composite backscattered signature. In both systems, portions of the radar energy reflect (backscatter) when they encounter changes in the physical and chemical properties of surface or subsurface materials. Varying the wave frequency and polarization (orientation of the electric field) of the EM wave during SAR flights will generate data across multiple bands, enabling increased target discrimination and characterization (Chapman and Blom 2013; Lasaponara and Masini 2013). Multiple GPR surveys over an area using offset grid orientations or different antenna frequencies can help characterize subsurface features (Conyers 2013).

SAR data provide an aerial or satellite view of archaeological landscapes or features using wavelengths ranging from meters to millimeters. Processing, calibrating, and geocoding the raw data result in an image where each pixel depicts the reflectivity of a portion of the ground (Chapman and Blom 2013). Unlike optical imagery, SAR is less susceptible to changes in

atmospheric conditions (e.g., increased cloud cover), can produce imagery during the day or night, and is useful in characterizing surface features or microrelief in forested environments (Lasaponara and Masini 2013). SAR's ability to penetrate the ground is strongly influenced by surface characteristics and by the soil's moisture content. Early uses of SAR in the 1980s had unexpected benefits for archaeology when NASA researchers flew over the Sahara and identified buried paleochannels below the sand (Lasaponara and Masini 2013). Airborne SAR (AIRSAR) conducted over Angkor Wat in Cambodia is one of the most notable uses of this technology in archaeology (Moore, Freeman, and Hensley 2007). Since the 1990s, SAR data aided in the identification of undocumented temples and an extensive water management system, and expanded the known settlement boundaries of Angkor Wat's well-integrated urban system. While archaeological applications of SAR are often geared toward settlement detection and the mapping of architectural features, the range of uses is increasing (e.g., to study Maya settlement (Garrison et al. 2011), irrigation structure, and wetland ecology (Adams, Brown, and Patrick 1981)). A notable area of recent research is in monitoring looting and structural deformation using time series collections. Today, many archaeological maps, landscape-scale geospatial analyses, and feature identification in remote regions utilize digital elevation models (DEMs) derived from shuttle radar topography mission (SRTM) data, which was collected in 2000 using interferometric SAR (InSAR). SRTM 90 m resolution DEMs provide nearly worldwide coverage and are freely available from NASA's Jet Propulsion Laboratory. Increasingly advanced technology and processing procedures will continue to expand the applicability of SAR to archaeological practice (see SAR (see SYNTHETIC APERTURE RADAR) for a more thorough discussion).

While not all surveys are successful at identifying features of archaeological interest, GPR is more common in archaeological practice than SAR. GPR has been utilized in archaeology since the 1970s, but its application has increased since

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0489

the turn of this century as the quality of the instruments and processing software improved. As radar waves encounter interfaces between materials with different dielectric properties, portions of the wave are reflected back to the surface antennae (Conyers 2013). The amplitude of the reflected wavelet is determined by the magnitude of difference in the properties of the two materials and the frequency of the antenna used. Mid-range frequency antennas (~400–500 MHz) are often suitable for archaeological studies. Higher-frequency antennas (~800–900 MHz) can provide higher-resolution data but at shallower depths; lower-frequency antennas (~100–200 MHz) are useful for identifying substrata or features in soils with a tendency to attenuate the wave's energy. All received energy from a single transect is plotted in two dimensions to form a radargram, which illustrates each received wavelet plotted by its relative amplitude and position in two-way travel time (Goodman and Piro 2013). Each transect's radargram is stacked sequentially into a 3D block of data and then sliced horizontally into "time slices" (the plan view at depth) in nanoseconds. Both the radargrams and time slices are important for analyzing and interpreting GPR data (Conyers 2012).

For many years, archaeologists considered dry sandy environments to be the best in which to conduct GPR surveys, particularly for resolving stone architecture. However, improvements in GPR technology and software, and in how one interprets archaeological features within GPR data, have resulted in more experimentation and innovative processing techniques. The amount of publications on archaeological case studies since the beginning of this century underscores how successfully GPR is being applied across diverse environments and soil conditions around the world. Conyers (2012) provides many examples and summarizations of GPR use and interpretation across archaeological contexts, including the identification of pithouse floors and perishable architecture, irrigation ditches and agricultural fields, burial trenches and unmarked graves, features and built surfaces within monumental earthen architecture, and a variety of stone architecture and urban environments. GPR has also been successfully used to identify and map

historical features, including building foundations and cellars, trash middens, wooden coffins, and, occasionally, mass graves and historical campsites. It is also useful for geoarchaeological studies, including mapping complex stratigraphy and identifying buried surfaces. Understanding the soil types present and ground conditions, such as the amount of recent saturation or types of mineral inclusions, is important for increasing the success of a GPR survey. See GPR (see GROUND-PENETRATING RADAR) for a more thorough discussion of its use in archaeological survey.

Sampling in Airborne Field

ROSA LASAPONARA
CNR-IMAA, Italy

NICOLA MASINI
CNR-IBAM, Italy

The “view from above” was first obtained in antiquity from elevated points, and later using balloons followed by kites, airplanes, rockets, and finally satellites. Historically, aerial photography was the first remote sensing tool extensively used for digital archaeology. The first aerial archaeological surveys were made on Rome in 1900 and on Stonehenge in 1906 by using balloons. Aerial photography dramatically improved before and during the world wars. In the first three decades of the twentieth century, pioneering aerial archaeological surveys were conducted in England and Sudan by O. G. S. Crawford, and in Syria by A. Poidebard.

For most of the twentieth century, aerial photography was the unique remote sensing tool for surveying emerging archaeological remains, as well as for detecting underground archaeological structures through the reconnaissance and interpretation of proxy indicators, such as crop-, damp-, soil-, and shadow-marks (Figure 1), which are the results of the physical and topographical interaction between buried archaeological deposits, soil and vegetation cover (Crawford 1929).

In particular, crop-marks are linked to the presence of buried walls and/or filled ditches in vegetated areas. They produce local variations in moisture and nutrient content and, consequently, in the growth of vegetation, which can be revealed by differences in height or color of crops.

Soil-marks are differences in soil color, which are particularly visible after ploughing as it brings to light dry material related to buried walls, or wet material related to pits and moats.

Damp-marks occur when the presence of archaeological deposits induce local changes in

the drainage capability of the soil and can be revealed by changes in color or texture.

Shadow-marks are produced by micro-topographic relief which is the residue of eroded shallow remains and earthworks, viewable from above when the sun is low in the sky.

Less frequent proxy indicators are snow-marks that occur as soil-marks mainly due to differences in bulk density, which determines the water balance and thermal behavior, and in turn impacts the presence of snow over archaeological deposits.

Today, multispectral images of archaeological marks can be produced thanks to spectral variations in specific channels or spectral indices.

The visibility of the above-mentioned proxy indicators has great intra- and inter-year variability due to changes in crop types and phenology, soil moisture content and other surface parameters. Additionally, the visibility of micro-relief depends on many factors, such as off-nadir viewing angle of the collected imagery, time of image acquisition, view geometry, sun angle (micro-topographic relief variations are more visible in early morning or late evening), and surface characteristics; in particular, the presence of vegetation can completely cover any micro-relief. These limitations can be overcome by an airborne laser scanner (ALS), also referred to as “light detection and ranging” (lidar).

Lidar is a quite recent (mid-1990s) remote-sensing technique used to measure terrain elevation and also to carry out a variety of new, promising applications including archaeology. Currently, a lidar survey could be carried out by using two different types of sensor systems: conventional or discrete echo scanners, and full-waveform ones. The first, generally, deliver only the first and last echo, thus losing many other reflections. The second are able to detect the entire echo waveform for each emitted laser beam, thus offering improved capabilities, especially in areas with complex morphology and/or dense vegetation cover.

Nowadays lidar is regarded as a well-established tool used for archaeological and cultural landscapes. The majority of published studies are

Figure 1 Aerial photograph of soil- and crop-marks related to a Neolithic settlement near Lucera, Italy. © CNR-IBAM/IMAA.

based on data collected by conventional ALS, for the management of archaeological monuments, landscape studies, and archaeological investigations, to depict micro-topographic earthworks in bare ground sites and in forested areas. Actually, the great potential of lidar in archaeology is mainly linked to its unique capability to penetrate vegetation canopies and identify archaeological earthworks and remains even under dense vegetation.

The recent discoveries of Arlen Chase in Belize (Chase et al. 2012) and Damian Evans in Angkor (Cambodia), the investigation of abandoned medieval villages in central and southern Italy by Rosa Lasaponara and Nicola Masini (see Figure 2; Lasaponara and Masini 2009), and the prospection of ancient landscapes in Austria by Michael Doneus et al. (2012) demonstrate the effectiveness of this technology for archaeological research in wooded areas.

The interpretation of lidar results to identify potential traces of cultural interest is based on shape, pattern, texture, and shadow. To this aim, it is crucial to process the point clouds and classify terrain and off-terrain objects by applying adequate filtering methods, in order to obtain a

very accurate digital terrain model (DTM) and to use appropriate visualization techniques (Hesse 2010) of digital models aimed at emphasizing changes in morphology and discontinuities in the landscape, and any kind of earthwork attributable to human activity.

Recently lidar has also been used for underwater archaeology with promising results, as in the case of a Roman harbor in Croatia by Doneus et al. (2012).

A valuable alternative to traditional aerial photogrammetry and lidar for operative use in archaeology is offered by the use of unmanned aerial vehicles (UAVs), which have several advantages, particularly low cost and the ability to cover large areas in a short time. Moreover, UAVs provide innovative vision and allow us to obtain very high-resolution products (orthophoto, digital elevation models) by using easy tools of image processing based on structure-from-motion (SfM) (Nex and Remondino 2014).

SfM is a range imaging technique that allows the estimation of three-dimensional objects from image sequences which may be coupled with local motion signals. Compared with conventional photogrammetry, which requires a single

Figure 2 Orthophoto and digital terrain model of the abandoned medieval village of Irsi (near Matera, southern Italy). © CNR-IBAM/IMAA.

stereo-pair, SfM needs multiple, overlapping photographs as input to feature extraction and 3D reconstruction algorithms. The usefulness of UAV-based investigation has increased, thanks to the capacity to integrate it other methods of remote sensing including geophysics, optical and synthetic aperture radar (SAR) remote sensing.

Additional remote-sensing technologies for sampling in the airborne field exploit sensors such as thermographic, ultraviolet, hyperspectral, and SAR, which provide information by exploiting regions of the electromagnetic spectrum invisible to the human eye (outside the range of 400–750 nm that is used in normal photography).

In particular, the capability of thermographic imaging to detect subsurface archaeological features is due to their contrast in thermal inertia with respect to their background, which depends on their composition, density, and

moisture content (Cassana et al. 2014). Aerial thermography proved to be an effective tool for the identification of pits, ditches, field boundaries, and shallow remains.

Hyperspectral sensors tend to enhance the contrast between archaeological deposits and their surroundings, exploiting those spectral bands more sensitive to moisture content and soil types.

Near-ultraviolet sensors generally acquire images at wavelengths ranging from 315–400 nm, and at low-altitude flight can detect features linked to soil- and damp-marks. Recently the use of SAR data in archaeology has shown the great potential of these technologies for site detection (buried or emerging archaeological remains) and monitoring, as well as for landscape archaeology.

Airborne SAR can overcome some limitations of optical imaging, providing the unique capability to “penetrate” into the soil (and to some

extent also the vegetation) especially in desert areas, providing a detailed map of subsurface structures and the paleoenvironment.

Sampling in Marine Field

E. CORY SILLS

The University of Texas at Tyler, USA

Sampling in marine field is beneficial in extracting a representative subset of information from an archaeological site. Complete archaeological excavations can be costly in marine and terrestrial settings, and are often unnecessary. Archaeologists commonly leave part of a site intact for future analysis as new, unforeseen technologies, and sampling strategies are devised. A well-formulated sampling strategy using an appropriate analytical technique can yield both cultural and environmental data to reconstruct the past.

The sampling of deposits in a marine setting within archaeology has advanced analytically by adapting methods from anthropology, biology, chemistry, ecology, environmental studies, geography, geology, and remote sensing. Due to the many lines of evidence required to interpret the past, sampling in a marine field is a collaborative endeavor. As a result of this integration of cultural and environmental information, complex questions regarding human–environment interaction can be addressed (see PALEOENVIRONMENTAL RECONSTRUCTION) (Johnson and Stright 1992). Archaeological investigations in coastal and marine environments reveal sampling advancements for inundated sites and the growing field of submerged archaeology on continental shelves throughout the world, including the Gulf of Mexico (Faught 2004; Masters and Flemming 1983).

Traditional terrestrial methods, such as shovel testing and small excavation units (see TERRESTRIAL EXCAVATION), have been successful in marine sampling, particularly in an inundated marine setting where the excavator can stand upright to complete the excavations, on sites with restricted access to diving gear, or in remote areas. Offshore shovel tests can clarify the extent of a site that has been impacted by sea-level rise where the majority of the site is presently underwater. The

underwater archaeological equivalent to shovel tests are cores (see CORING) and induction dredging. These sample the seafloor at known archaeological sites. Cores are useful in extracting environmental data, whereas dredging is the preferred method for extracting cultural information.

Sediment samples collected from shovel tests, excavation units, cores, and dredging yield cultural and environmental data for reconstructing and evaluating ancient landscapes. Typically, sediment samples are extracted from cores or from the walls of excavation units (see SAMPLING IN ENVIRONMENTAL STUDIES). These extracted samples are analyzed using sedimentology. Particle size analysis is used to determine the amount of sand, silt, and clay. The differences in particle size distributions of sediment can aid in reconstructing relict rivers, levees, and other landforms (Johnson and Stright 1992). Loss-on-ignition, magnetic susceptibility (see MAGNETIC SUSCEPTIBILITY), and macroscopic examination of sediment from underwater excavations are additional types of sediment analysis. Loss-on-ignition measures the percent of organic material in sediments and is particularly useful for organic-rich sediments, such as in areas with peat deposits, to determine the rate of sea-level rise (see SEA-LEVEL CHANGE). Magnetic susceptibility can determine whether areas have been magnetized, usually from the heat from fires. Macroscopic analysis of sediment is where vegetation that is preserved in the sediment is identified through a microscope. This method is most useful in organic environments where there is visible plant structure. Increasingly, pollen analysis (see DATING POLLEN and PALYNOLOGY) is used to date as well as reconstruct environments. Additionally, microfossils including diatoms (see DIATOMS), foraminifera, and ostracods (see OSTRACODS AND CLADOCERANS) are analyzed because they are sensitive indicators of sea-level fluctuations.

Sediment chemical analysis using inductively coupled plasma mass spectroscopy (see ICP-MS AND MATERIAL ANALYSIS) can be adapted from terrestrial archaeology for a marine setting. The analysis of the spatial variation of concentrations

DOI: 10.1002/9781119188230.saseas0514

of elements is well established in determining activity areas on terrestrial archaeological sites. The sampling of marine sediment from the seafloor of an archaeological site can identify activity areas not apparent in the archaeological record, such as areas for food preparation and disposal, hearths, the remains of meals, and ash from fires.

The list of sampling methods discussed above for a marine field is not exhaustive. All of the methods mentioned have been developed to study intertidal, near-shore, and offshore deposits, which indicates the versatility of these methods as they are applied at various scales.

Satellite Hyperspectral and Multispectral Imaging

GEERT VERHOEVEN

Ludwig Boltzmann Institute for Archaeological
Prospection and Virtual Archaeology (LBI ArchPro),
Austria

What's in a name?

Satellite imaging is a part of remote sensing (see AIRBORNE REMOTE SENSING), which can be broadly defined as the collection of data about a scene or object without having direct physical contact with it. In archaeology, remote sensing is a general name given to all techniques that use propagated signals to observe the Earth's surface from above. Based on their specific characteristics, remote sensing techniques can be classified in different ways: imaging versus nonimaging, passive versus active, optical versus nonoptical, airborne versus spaceborne. Whereas passive remote sensing systems capture naturally occurring radiation, active systems produce their own radiation. Airborne systems operate from within the Earth's atmosphere, while spaceborne systems deploy a sensor mounted onboard a spacecraft (often a satellite) that orbits the Earth. When dealing with an imaging system, the output is an image, whereas nonimaging systems can deliver sounding data or emission spectra.

Although exceptions exist, archaeological satellite multi- and hyperspectral imaging generally refers to the amalgam of passive remote sensing techniques that capture a specific part of the Earth's reflected solar energy or self-emitted thermal energy from space, and turn that into a (digital) image. In addition, these spaceborne imagers only operate in the optical electromagnetic spectrum, which conventionally incorporates the complete ultraviolet to infrared bandwidth, comprising radiation with wavelengths between 10 nm (0.01 μm) to 1 mm (1000 μm). However, remotely-sensed imaging in the optical range usually begins at the

visible waveband (i.e., 400–700 nm). Together with the near-infrared (NIR; 700–1100 nm) and short wavelength infrared (SWIR; 1.1–3 μm), this waveband is known as the solar-reflective spectral range because imagery is predominantly generated by reflected solar energy. The neighboring mid-wavelength infrared (MWIR; 3–6 μm) range is considered an optical transition zone, as the solar-reflective behavior slowly shifts in favor of self-emitted thermal radiation. In both the long wavelength infrared (LWIR; 6–15 μm) and far/extreme-infrared (FIR; 15 μm to 1 mm), the imaging process is almost uniquely governed by the thermal electromagnetic radiation emitted by the scene objects themselves. As a result, the MWIR to FIR optical region is commonly denoted the thermal region. Finally, “multi-” and “hyperspectral” refers to the fact that different spectral bands/channels capture the reflected or thermal energy.

Spectral imaging (which is a term that covers both multi- and hyperspectral imaging) starts as soon as optical electromagnetic radiation is detected and digitized in four spectral bands (see MULTISPECTRAL AND HYPERSPECTRAL IMAGING). The amount of captured bands is also one of the distinguishing factors that denotes a spectral imaging system as “multi” or “hyper”. A multispectral device digitizes the reflected (and/or emitted) electromagnetic radiation in around 4–10 adjacent spectral bands that are about 100 nm wide and often feature a small spectral gap in between them (e.g., 730–850 nm, or 1050–1200 nm). Hyperspectral imaging extends this multispectral concept by capturing spectral data in at least 10 (nearly) contiguous (i.e., adjacent and not overlapping) narrow spectral channels.

Sensor characteristics and their influence

Not all spaceborne images are created equally, and as such, not all have the same archaeological potential. This becomes clear when one understands that digital image pixels always

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

© 2018 John Wiley & Sons, Inc. Published 2018 by John Wiley & Sons, Inc.

DOI: 10.1002/9781119188230.saseas0517

represent averages in time, space, and spectral range. The integration time or shutter speed of the imager determines the sampling of the time dimension. The two other sampled dimensions define important image characteristics known as spatial resolution and spectral resolution, respectively defining the minimum distance between distinguishable objects and the spectral details that can be resolved in the image.

Although the final spatial resolution of an image depends on many factors, one of the key factors is the so-called ground sampling distance (GSD). Most imaging sensors consist of individual photosensitive elements or photosites. The distance between a photosite's center and the center of the neighboring photosite is denoted the "detector pitch". The GSD is the corresponding distance projected onto the Earth's surface, stating the horizontally or vertically measured scene distance between two consecutive sample locations (even though the term is technically wrong, pixel size is often used as a synonym for GSD). Amongst other factors, the GSD is determined by the scene's local topography, the viewing direction of the camera (nadir or off-nadir), the focal length of the lens, and the distance of the camera to the scene. In general, spaceborne images are acquired by platforms in orbits between approximately 160 km and 2000 km above the surface of the Earth. A satellite operating in a lower orbit will therefore be capable of generating a smaller GSD.

Concerning satellite imagery, the so-called panchromatic image always features the highest spatial resolution. This is a greyscale image created by one spectral band that is sensitive to more or less all ("pan") wavelengths (or colors, hence "chroma") of visible electromagnetic energy. Virtually every passive spaceborne imager creates a panchromatic image. The spectral resolving power of such a panchromatic band as well as any spectral channel is measured by the full width at half maximum (FWHM). The FWHM of a band quantifies its spectral bandwidth at 50% of its peak responsivity. For example, hyperspectral bands often have a FWHM of circa 15 nm, while multispectral sensors capture energy in bands with 100 nm FWHM. To sufficiently resolve small spectral features, the spectral bands should have a width smaller than or comparable to the spectral

details in the signal and be placed in the correct part of the spectrum. Since the total amount of incoming radiant energy is related to a band's FWHM, the photosites that generate spaceborne multispectral images are commonly 4–16 times larger compared with the spectrally-wide panchromatic band (350–400 nm FWHM). Due to the square nature of most photosites, this translates to a GSD that is two to four times lower for multispectral images compared with their panchromatic counterpart.

Although most optical spaceborne imaging systems are multispectral, hyperspectral imagers do also exist. Due to their higher spectral resolving power (i.e., smaller FWHM for every band), hyperspectral imagers sample over an even larger spatial extent to obtain the necessary incoming electromagnetic energy to produce a decently exposed image. As a result, spaceborne hyperspectral imagers will always feature a coarser spatial resolving power than their multispectral counterparts. To overcome this physical tradeoff between spectral and spatial resolution, spectral data are often fused with panchromatic spatial details in a procedure called pansharpening. In the SWIR wavelength range and beyond, the amount of reflected or self-emitted energy is so low that imagers have to increase their spectral bandwidth and/or their detector pitch to acquire enough energy.

Digitally capturing a scene also means that the sampled analogue signal needs to be quantized to discrete data numbers. The bit depth of this quantization determines the achievable tonal range of the image, thereby providing images with a radiometric resolution. Although the temporal sampling is determined by the integration time during image acquisition, the temporal resolving power of a remote sensing imaging system generally refers to the repeat period or the capability to view the same scene at regular intervals.

Archaeological use

Spaceborne imagery used for archaeological practice comes from either non-military or declassified military sensors. Due to their often surprisingly high spatial resolution (Fowler 2010), the latter category is an essential resource for all

studies that focus on the change and monitoring of the landscape or in a general supporting role to produce base maps (certainly in those areas lacking conventional aerial footage). However, this imagery cannot be categorized as multi- or hyperspectral since it generally comprises only one panchromatic band. In addition, these images are also spatially, spectrally, and radiometrically outclassed by many present-day civilian products (Scardozzi 2016). Although aerial footage still has the edge in terms of spatial resolution, the steady technological leaps of spaceborne imagers has resulted in, by 2017, GSDs of the order of 40 cm.

It is the combination of this improved GSD, the inherent synoptic perspective (i.e., footage with a very large spatial coverage), and the spectral capabilities which, together with the improved (online) access, provides many interesting opportunities for landscape archaeologists when compared with conventional aerial imagery. Besides, satellites can image areas that have limited or no access due to airspace restrictions or bureaucratic red tape. As a result, many present-day spectral products are used for archaeological prospection. Since buried archaeological residues can change the chemical and physical properties of the local soil matrix, their presence might be disclosed by growing- or ripening-induced differences in the reflectance or height of vegetation on top of the remains (i.e., vegetation marks), or distinct tonal differences in the ploughed soil (soil-marks). Dedicated spaceborne imaging devices enable the comprehensive mapping of such plough-levelled sites through these proxies of soil- and crop-marking. Examining the remotely sensed imagery for such pertinent archaeological information can help to develop knowledge about people in the past. Here, the fundamental difference of multi- versus hyperspectral imagery again plays an important role. Obviously, more and narrower spectral bands have a greater potential for detecting subtle spectral reflectance differences in the soil and vegetation cover. On the other hand, hyperspectral images suffer from spatial resolution constraints that have a lesser effect upon multispectral products. For example, the hyperspectral imager CHRIS onboard the European Space Agency's 2001-launched Proba-1 satellite acquires 19 programmable spectral bands in the 415–1050 nm range. However, its 17 m GSD only renders the

imagery useful for mapping very broad landscape features such as paleochannels, road complexes, or ancient water management structures. Even though many civilian spaceborne hyperspectral imagers with improved spatial resolving power have been announced in the past years, none are currently operational.

Although the wider bandwidth of the multispectral products might average subtle spectral details away, the fact that data are generally recorded at well-placed spectral positions in the NIR and SWIR still makes them very suitable for visualization of reflectance differences between diverse soils and health states of vegetation. For instance, the imaging sensors onboard DigitalGlobe's commercial WorldView-3 satellite provide panchromatic imagery with 0.31 m GSD and eight multispectral bands in the 400–1040 nm range. The latter feature a GSD at a nadir of 1.24 m and even comprise special yellow (585–625 nm) and red edge bands (705–745 nm) for vegetation mapping. Additionally, WorldView-3 also provides another eight multispectral bands at 3.7 m GSD in the SWIR region (1195–2365 nm). When pansharpened, any of these spectral images can be very appropriate for identifying archaeological features, mapping landscape structures, assessing spatial relationships between sites and their environment, as well as identifying and monitoring threats (such as looting). However, when one needs to spatially resolve the soil and crop marks that result from very small features (such as pits and postholes), an airborne vantage point (see AERIAL PHOTOGRAPHY) still remains superior. They do, however, generally lack the synoptic perspective of spaceborne footage. Even for decade(s)-old spaceborne spectral imagery featuring GSDs of at least a few meters, this landscape-centered perspective remains a major advantage in archaeological practice.

In the future, the regular data acquisition by these spaceborne instruments and the ever-improving spectral and spatial quality of newly launched imagers will only continue the growth of multi- and hyperspectral satellite imagery as a primary archaeological data source. Together with a possible decrease in purchasing costs and the ongoing advances in image processing techniques, they will continue to deliver increasingly useful tools for archaeologists to exploit.

Soil Penetrometry

ANTHONY P. GRAESCH

Connecticut College, USA

Penetrometry concerns the attributes and behaviors of surface and subsurface soils. At its most basic, penetrometry is the measurement of soil resistance for the purpose of assessing soil compaction. In general, the extent to which soil is compacted has relevance to an array of earth sciences, including geomorphology, sedimentology, pedology, and glaciology. Soil compaction is also of interest to the fields of geoscience that are more directly concerned with the qualities of soil as they affect or are affected by human behavior, including edaphology, agronomy, and engineering geology. In archaeology, researchers have been particularly attentive to the ways that variable soil compaction provides insights into the agricultural potential and use of ancient landscapes, as well as the activities that create and transform cultural features, such as house floors, ancient roads, and cemetery grave plots.

Penetrometers are the instruments employed in soil penetrometry and come in several forms, with some notable differences in portability, precision, measurement, and cost (Figure 1). The simplest of penetrometers are manually operated and measure how much force a soil is able to withstand before giving way to a penetrating rod. Sometimes also marketed as “soil compaction testers,” these instruments are typically the least expensive and most portable, although they are also less precise and capable of only simple characterizations of soil behavior.

The pocket penetrometer, for example, weighs no more than 150 grams and can easily be transported and used for frequent on-site measurement of soil compaction. Operation requires minimal training: holding the instrument with only one hand, the user grips the cylinder and places the tip of the piston on the surface of the soil to be measured. Pushing downward at a right angle compresses a calibrated stainless steel

spring, forcing an indicating ring to slide up the piston. At the point that a piston calibration mark sinks to the same level as the soil surface, the user stops exerting downward pressure and records the measure as indicated by the new location of the indicating ring against a piston-mounted scale (see Figure 1). Given the simple design of the instrument, readings are best regarded as approximations of actual soil resistance, although manufacturers suggest that accuracy to 0.122 kg/cm² (1.74 PSI or 0.125 tons/ft²) is possible. For weak soils and sediments (e.g., uncompressed beach sand), an adapter can be attached to the end of the piston.

Dial penetrometers are larger than their pocket counterparts, although they are similarly operated by manually applying downward pressure to measure soil resistance as a proxy for soil compaction. An important distinction is that dial penetrometers are capable of measuring soil compaction at known depths below the surface. The instrument's t-shape handle features a dial gauge that displays soil resistance as measured in PSI by a cone tip at the end of a 60-cm stainless steel rod. Softer soils often require a larger tip, whereas harder soils can be assessed with a smaller cone. Most dial penetrometers, however, are capable only of measuring resistance to an accuracy of 50 PSI (3.52 kg/cm²).

More complex instruments used for penetrometry, such as cone penetrometers, are considerably larger and require mounting to wheeled or tracked vehicles (e.g., a truck, tractor, or trailer), usually equipped with hydraulic leveling and land anchors so as to compensate for the reaction of hydraulically driving a testing probe into the ground. In cone penetrometer testing (CPT), ease of instrument portability is sacrificed for greater reliability of measurements. For example, the use of a hydraulic piston to drive the instrument's cone-tipped rod downward eliminates variability in the rate at which force is exerted on manually operated instruments, like dial and pocket penetrometers. While the cone measures penetration resistance (q_c), the probe rods on many CPT instruments are also equipped

Figure 1 Three types of penetrometers available to archaeologists: (a) pocket penetrometer; (b) dial penetrometer; and (c) cone penetrometer.

with friction sleeves that measure lateral friction resistance (f_s) as the probe extends downward. The relationship of side friction to tip resistance (R_p) can be used to construct soil behavior profiles, although this classification should not be confused with analysis of grain size distribution as determined by the Unified Soil Classification System (USCS) (Robertson and Cabal 2015).

Additional sensors can be added to the cone used in CPT, thus greatly expanding the kinds of data collected and affording fuller characterizations of subsurface soils. Piezocone penetrometer testing (CPT-U), for example, employs a cone equipped with porous elements that measure soil pore pressure (u). Other sensors afford conductivity measurements (CPT-C) as well

as seismic shear wave and compression wave velocity measurements (CPT-S).

Although penetrometers have been around since the 1950s (Mathieu and Toogood 1958), implementations of penetrometry in archaeological inquiry were rare prior to the 1990s. Since, a modest corpus of research has emerged, and the analytical potential of penetrometry is evident in a wide array of questions and types of field investigations to which penetrometry methods have already been applied. For example, CPT data have been shown to be both reliable and accurate for determining soil stratigraphy and topographic features of buried landscapes in Belgium (Missiaen et al. 2015). Although CPT methods do not yield insights that fully

substitute for those derived from conventional coring methods, they are highly complementary and may allow for even more efficient sampling strategies when profiling subsurface sediments. Elsewhere, penetrometers have been used to assess and map variable compaction of soils for the purpose of locating surface and subsurface cultural features. Some examples include the use of pocket penetrometers to search for cart paths connecting eighteenth century plantations in rural Delaware (Burrow et al. 2014), and the use of dial penetrometers to reveal the locations and delimitations of burial plots in Colonial settler cemeteries (Trinkley 1999).

Penetrometry has also been successfully incorporated into the basic suite of data recovery methods applied during formal excavation. In the Pacific Northwest, pocket penetrometers have proven useful for quantifying otherwise subjective assessments of variable strata compaction during the investigation of ancient house features. Indeed, compaction data gathered with penetrometers have aided in the task of identifying house floors in noncontiguous excavation units, and for the purpose of collecting context-sensitive sediment samples for macrobotanical and microartifact analyses (Graesch, Shankel, and Schaepe 2015).

Penetrometry has also played a role in the study of recent site formation processes that adversely impact cultural resources. CPT data, for example, have been used to assess changes in the compaction of sediments after heavy machinery is operated on the surfaces of archaeological sites (Ardito 1994). Elsewhere, penetrometers have been incorporated in experiments concerning the effects of farm equipment on fragmentation rates of pottery and bone artifacts (Dain-Owens et al. 2013), as well as taphonomic research addressing the impact of armadillo burrowing in archaeological deposits (Araujo and Marcelino 2003).

In all of these cases, archaeologists have used penetrometers that were designed to meet the needs of geotechnical applications, particularly those based in agronomy and engineering geology. Given recent demonstrations of the relevance of penetrometry to archaeological inquiry, it is reasonable to expect that further developments in penetrometer technology may be driven by the specific needs of archaeologists. Archaeologists are already working to develop instruments that

have the portability of manual penetrometers but the sensory complexity and accuracy of CPT instrumentation (Russo 2015). Such penetrometers could greatly improve the task of detecting buried cultural deposits in places inaccessible by vehicles.

Soil Phosphate Chemistry

DANIEL A. BAIR

University of California, Davis, USA

RICHARD E. TERRY

Brigham Young University, USA

Lack of artifacts in archaeological settings

Many archaeological sites were slowly abandoned and artifacts were moved or taken from their locus of use either in ancient or modern times. Archaeological interpretation is difficult when artifacts are displaced or altogether missing. In the humid tropics, in particular, high decomposition rates result in the complete loss of perishable artifacts, particularly those related to food products. Analysis of ancient human activities at archaeological sites can be facilitated by determination of certain elemental residues that persist in the soils and floors. Chemical residues of ancient activities represent invisible yet critical artifacts of ancient human lives.

Phosphorus concentrations in soils and floors

Examination of soil chemical concentrations can elucidate areas where past activities repeated in a given locale would have left elevated concentrations associated with byproducts of such activities. Increased levels of phosphorus (P) is one of the most archaeologically significant anthropogenic alterations of soils (Holliday 2004). Phosphorus is a structural component of phospholipids, nucleic acids, and many other biological molecules within living tissues. Anthropogenic P originates from plant and animal materials gathered for food and brought to settlements for consumption. As food, animal, and human wastes are disposed, the organic P constituents decompose and inorganic phosphate ions are released, only to become readily fixed

or adsorbed on the surfaces of soil particles at the site of accumulation (Barba and Ortiz 1992; Terry et al. 2000). These fixed forms of phosphate are highly insoluble and resistant to physical and chemical processes of leaching, oxidation, and reduction. Fixed P remains stable in soil and most occupation surfaces for centuries (Holliday 2004; Parnell, Terry, and Golden 2001). As humans concentrate organic matter in specific locations and residues from the organic matter are worked into the soil, inorganic P concentrations can increase significantly compared with the original P concentrations of occupation surfaces. Therefore, elevated P levels in soils in comparison to background concentrations are predictors of ancient food-related human activities which can include storage, preparation, consumption, and waste disposal, and the identification of features such as burials, gardens, animal pens, and hearths (Terry et al. 2000). Phosphorus at or near background levels are indicative of non-food-related activities such as patio sweeping, high-traffic pathways, and sleeping areas (Barba and Ortiz 1992; Parnell, Terry, and Sheets 2002).

Background P concentrations in occupation surfaces

Human activities can either increase the P content of soils and floors as organic materials are gathered and processed, or depress the P levels by using materials that were naturally low in P to construct dwelling floors and plaza surfaces. Collection of natural control soils outside of a settled area may not provide appropriate background concentrations of anthropogenic elements. Natural soils likely contain higher levels of P and other elements than excavated fill or plaza stucco derived from burnt limestone. Some researchers have estimated the background element concentrations of the occupation surface by calculating the average concentrations of a portion of samples that were lowest in P concentration (King 2008; Dahlin et al. 2007; Parnell et al. 2001; Terry et al. 2004). The soil and floor samples lowest in P and

DOI: 10.1002/9781119188230.saseas0538

trace elements represent areas of lowest chemical enrichment by ancient human activities.

Soil P fixation

Phosphorus in soil exists in three pools of solubility or plant availability (Hopkins 2015). The dissolved phosphate pool is found in soil solution and is available for uptake by plants and microorganisms. The pool of labile P includes weakly sorbed inorganic phosphate ions, soluble P minerals, and readily decomposable organic P compounds that slowly release phosphate ions to the soil solution during the course of a growing season. The largest pool of soil P is the nonlabile or fixed P that includes strongly sorbed P, phosphate minerals of very low solubility, and P contained in humus molecules that are highly resistant to decomposition and mineralization of P. Phosphorus that is deposited in the soil by human activities eventually becomes fixed, which means that it is strongly sorbed, bound or highly insoluble, and thus can be preserved in the soil for centuries as a marker of those ancient activities.

The analysis of P is a useful tool in geoarchaeological study because it is fixed in a wide range of soils. Precipitation and sorption of P occurs rapidly in soils and floors due to equilibrium chemistry. The soil solution can only hold a finite amount of dissolved P. The reverse reaction (solubilization of precipitates and desorption of labile P) also occurs, with P coming back into soil solution. The rate of this reaction accelerates when nonequilibrium conditions exist due to P being removed from soil solution.

Phosphorus fixation is defined as the formation of solid phase P compounds formed by chemical precipitation reactions or strong adsorption to soil minerals. In neutral pH soils to alkaline soils, several calcium (Ca) phosphate minerals form. The greater the interaction of P with Ca, the lower the solubility of the mineral. Eventually the highly insoluble rock phosphate mineral known as apatite forms in the soil. The high calcium carbonate (CaCO_3) levels in some soils and especially in lime stucco floors promotes P sorption on particle surfaces and increases the precipitation of soil solution P as Ca–P minerals (Hopkins 2015). Phosphorus combines with Ca and magnesium (Mg), which are typically

found at high concentrations in alkaline soils. These Ca and Mg phosphates are poorly soluble at high pH. In neutral to acid soils, phosphate ions react with iron (Fe) and aluminum (Al) to form highly insoluble Fe and Al phosphate minerals. Examples of these fixed phosphate minerals include strengite ($\text{FePO}_4 \cdot 2\text{H}_2\text{O}$), vivianite ($\text{Fe}_3(\text{PO})_2 \cdot 8\text{H}_2\text{O}$), and variscite ($\text{AlPO}_4 \cdot 2\text{H}_2\text{O}$).

History of phosphate testing in archaeological settings

Geochemical analysis of ancient activity areas in archaeological studies extends back to the early 1930s and 1940s in Europe, when Swedish agronomist Olof Arrhenius reported the relationship between elevated soil phosphate levels and sites of previous human occupation. Activities such as food preparation, storage, disposal, animal confinement, and the manuring of fields and gardens leave distinct chemical impressions that can remain relatively immobile in the soil for centuries. Soil samples collected prior to excavation can be analyzed and chemical patterns determined, and mapped, to prospect for archaeological features of interest. An example of soil phosphate prospection is a shovel-test survey in an effort to locate a lost historic farmstead in northwest Virginia (Rypkema et al. 2007). The patterns of phosphate accumulation in occupation soils and floors revealed ancient ceremonial and household activity areas at Templo Mayor in central Mexico (Barba et al. 1996). King (2008) conducted geochemical analysis of residues in Post-classic floors and waste deposits to provide information on food-sharing, commensality, and household social organization in coastal Oaxaca, Mexico.

The karst topography of the Maya Lowlands provides an ideal setting for phosphate investigations. Calcium is naturally rich in the thin soils surrounding the ancient Maya settlements and is the means for P fixation in these soils. Plaza floors, causeways, and the floors of elite households and buildings were plastered with stucco, produced from burned limestone, which is naturally low in P.

Extractable P analysis of soils and floors of both ancient and contemporary households in

Mesoamerica have demonstrated that household activity areas contain different levels of P that have helped to identify areas of food preparation, consumption, storage, waste disposal, sleeping quarters, workshop activities, and ritual and funerary activities (Terry et al. 2004). Geochemical analysis of soil phosphate prior to excavation has been used at Piedras Negras, Guatemala and other sites as a prospection tool to identify waste middens and other important features (Terry et al. 2000). Similarly, Parnell et al. (2001) reported a significant positive correlation between sherd density in test pits and surface soil P concentrations. At Cerén, El Salvador, Parnell et al. (2002) found the highest P concentrations (>50 mg/kg) in middens, while the lowest P concentrations were discovered in the samples from pathways (about 5 mg/kg), where constant foot traffic and sweeping prevented P accumulation. Thus, well-used pathways and heavily used activity areas tend to be low in extractable P. Ceremonial, feasting, and marketplace activities in open plazas have recently been identified by chemical analyses of gridded soil samples (Dahlin et al. 2007).

Phosphorus analyses

There are several laboratory and in-field methods to determine phosphorus concentrations that have been used in archeological studies. These analyses are modifications of standard soil analyses used in determining the total P content of the soil or the extractable P that is related to plant uptake in agriculture.

Total phosphorus

Total P can be determined with chemical digestion of soil. This method requires the use of harsh chemicals, nitric and perchloric acid, and would be limited to a laboratory setting. The digestion of soil is also time- and labor-intensive. Total P analyses may provide information on human activities, but the natural mineral constituents of soil and floor particles may overwhelm the trace levels of P deposited by human activities (Parnell et al. 2001; Coronel et al. 2014). Total digestion with nitric and perchloric acid solubilizes all of the mineral and organic P constituents that are,

for the most part, neither plant available nor anthropogenic. Parnell and colleagues (2001) demonstrated that high concentrations of total P levels from a group of 35 samples from an ancient occupation surface at Piedras Negras were two orders of magnitude greater than the levels of P extracted by dilute acid. The total P analysis includes phosphate minerals that are naturally sorbed by soil particles, whereas anthropogenic P would most likely be found adsorbed to the surfaces of soil particles. Relative concentrations and spatial distributions of chemical residues are key to the identification of human activity areas.

Extractable phosphorus

Soil scientists often conduct soil nutrient availability tests to estimate the amounts of resident P that the soil can provide for crop growth. Soil samples from the field are extracted with various dilute acid or alkaline solutions that remove the pools of soluble and labile P that are likely to provide plant nutrition during the growing season. Dilute acid and mild alkaline extraction procedures remove a portion of the phosphorus adsorbed on the surfaces of soil particles. Variations of P extraction methods have been designed and simplified to use in the field laboratory, (Rypkema et al. 2007; Terry et al. 2000).

The extractable P concentrations vary greatly with the type and strength of the extracting solution. In each extraction procedure, the portion of phosphorus analyzed is affected by soil acidity or alkalinity, organic matter percentage, clay content and soil type, and other physical and chemical properties of the soil. For these reasons, the magnitude of extracted P concentration differs with the procedure and with soil type and geographical origin.

Terry et al. (2000) and Coronel et al. (2014) subjected soils of household middens, patios, and pathways from Piedras Negras to three different extraction procedures and two total P analysis procedures, including nitric and perchloric acid digestion and X-ray fluorescence (pXRF). While the three extraction procedures identified high soil phosphorus levels surrounding household middens and low phosphorus concentrations in patio and pathway soils, the Mehlich II dilute acid extraction provided the greatest percentage

difference in concentration between background samples and midden samples. The greater contrast between midden and average P values determined by the extraction techniques illustrates the fact that anthropogenic P is most likely to be in the form of extractable P absorbed on the surfaces of soil particles rather than the total P contained within the mineral and organic parent materials of the soil (Coronel et al. 2014). Several studies have shown that the extractable phosphate procedure is not only better because of more interpretative detail in the resulting chemical patterns, but it is also more cost-effective and functional in both formal and field laboratory settings.

Soil Survey

ANTHONY R. TRICARICO

University of South Florida, USA

Contemporary applications of soil survey in archaeology intersect the boundaries of theoretical interdisciplinary geoarchaeology (see GEOARCHAEOLOGY) and increasing methodological emphases on macro- rather than micro-level scales of analysis. Soil survey has been used in soil mapping since the early 1700s, but spatial representation of soil attributes in documentary evidence had considerably earlier origins. Documentary records show that soil properties had been applied to delineate land ownership as early as the fourth century in China (Brevik et al. 2016). However, its widespread use in pedological investigations of soil distribution and the relationship between landscape and cultural interaction dates back to the early nineteenth century. The creation of nationalized soil survey programs in the twentieth century (Brevik et al. 2016) indicates that soil survey had become an essential component to soil science and research at both the academic and government levels (Holliday 2004). Holliday (2004) argued that soil survey and mapping have been relatively underutilized in geoarchaeological investigations. However, geochemical investigations of land-use patterns within the last decade have increasingly relied on soil surveys to inform differential spatial patterns of past human–environmental interaction (Wilson, Davidson, and Cresser 2008) (see ENVIRONMENTAL ARCHAEOLOGY). Soil survey and mapping has seen an infusion of new digital methodologies emphasizing the quantitative power of spatial soil prediction (Gessler et al. 1995; McBratney, Mendonça Santos, and Minasny 2003; Scull et al. 2003; Mulder et al. 2011; Demattê and da Silva Terra 2014).

Traditional soil survey requires the application of three different methods in order to properly record spatial variations in soil series. First, one must conduct a preliminary, direct observation of landscape data and corresponding soil

characteristics. This involves investigating aerial photographs or satellite imagery of the study area to analyze known geological features, vegetation changes, and their impact on the distribution of potential soil classes. Next, soil attributes must be observed in the field and used to construct a generalized model of soil variation (Scull et al. 2003). Holliday (2004) defines these attributes as a soil series. Each soil series is investigated based upon such characteristics as: type, thickness, color, texture, structure, pH, and mineralogy (Holliday 2004). Finally, a soil survey must use known distinctions in soil series to create a generalized spatial model of soil association across the landscape, capable of predicting variation in unobserved areas (Scull et al. 2003; Holliday 2004).

National soil mapping programs employ this qualitative means of soil survey to record variability in soil resources. Soil surveys have been used for a considerable number of non-archaeological applications, including land-use planning, soil conservation, and land evaluation. These surveys produce maps at differing scales, which could prove problematic when creating regional evaluations of soil attributes. However, soil surveys have traditionally collected a variety of information regarding soil properties, which is useful to geomorphological and geoarchaeological investigations.

Specifically, loess thickness and origin, soil texture, and soil erosion have proved particularly helpful (if underutilized) in evaluating the influence of geomorphology on the preservation of archaeological data. Theoretically, soil scientists and geoarchaeologists have traditionally been divided on how they approach spatial soil relationships. Pedologists have conducted soil surveys that emphasize the vertical dimensions of soil rather than spatial, horizontal variability (Holliday 2004). Holliday (2004) argued that soil survey is thus problematic for reconstructing past relationships between geomorphology and the spatial patterning of archaeological material.

Archaeology's deep-temporal understanding of soil development and its historical implications may be its greatest contribution to the creation

of future soil maps and the refinement of soil survey methods. Holliday (2004) emphasized four distinct uses of soil surveys in archaeology. First, soil surveys have proved useful in site analysis. Often, soil surveyors have recorded potential sites and their location during initial surveying. At other times, the mapping of drainage has helped archaeologists locate the most likely locations in which to find additional sites. Second, distributions of soil series have been used as a predictive tool to locate sites based upon known locations of other sites relative to certain soil series. Archaeologists have utilized soil maps to predict cultural areas based upon frequencies of soil series. Third, cultural resource management (CRM) has driven increased demand for the recording of spatial soil relationships based upon differential geomorphology. Fourth, soil surveys have been used by archaeologists to analyze the distribution of landforms and relative age of the landscape (Holliday 2004). Soil surveys have thus been a cornerstone of historical ecology studies. Archaeologists use variation in soil attributes relative to geomorphology to inform the degree and legacies of ancient and historic land-use practices.

Geochemical approaches are often combined with traditional analyses of soil surveys to further elucidate the spatiality of human activity patterns. Wilson et al. (2008) conducted multi-element analyses of soil samples to evaluate inter-site variability in activity patterns at various abandoned farms in the UK. Wilson et al. (2008) concluded that human activity areas can be determined by analyzing variations in concentrations of Ba, Ca, P, Zn, Cu, Sr, and Pb. Wilson et al. (2008) found that Hg and Pb concentrations can best identify areas of craft production, while Sr and Ca can identify agricultural areas, and K, Rb, and Th can indicate settlement areas. Soil survey informed inter-site variability in soil series, geomorphology, and hydrology, which can affect the spatial distribution of elemental concentration, conflating the role of archaeological activity patterns. Soil survey allowed Wilson et al. (2008) to comment on the effect that postdepositional soil-forming processes versus anthropogenic element loading had on the overall picture of contemporary landscape conditions.

Geoarchaeological investigations in Antigua, West Indies, use soil survey and geochemistry to evaluate the long-term landscape legacies

of nearly 300 years of sugarcane monoculture. This study uses geomorphology and elemental signatures of intensive agricultural production to contribute more generally to the archaeological understanding of land degradation resulting from agricultural abandonment. Soil survey is being used to inform the degree of contemporary landscape erosion, in efforts to help mitigate landscape instability. Soil survey has also contributed greatly to archaeological investigations analyzing the impact of past human–environmental interaction on the lived experiences of contemporary populations.

The use of soil survey and mapping in archaeology has been cautioned by Holliday (2004) in accordance with two primary confounding principles. The generality of soil maps limits their utility for archaeological investigations. Holliday (2004) argued that a lack of consistency in scale severely limits the use of soil survey in analyzing site-specific research questions. Generalized grouping of soil classes across the landscape also confounds the complexities of spatial distribution. Soil surveyors tend to group soils into a limited number of different classes based upon associations between their attributes. For this reason, Holliday (2004) noted that boundaries between soil classes on maps are rather arbitrarily and subjectively constructed. Therefore, any archaeological site that is smaller than the scale of the map will be hindered by these problems. Micro-scale investigations of landscape complexities in archaeology are thus limited. Holliday (2004) alluded to the greater applicability of soil survey in macro-scale investigations.

Soil survey in archaeology has begun to shift from qualitative descriptions of soil attributes to quantitative analyses and predictions of the spatial distribution of soil series. McBratney et al. (2003) argued that the field began to transition in the last 20 years from reliance on knowledge-based modeling. Gessler et al. (1995) prominently called for the creation of a statistical model to relate geomorphological features with variations in soil attributes. This process included the development of a new systematic field-sampling strategy to construct a more accurate soil–landscape model. Gessler et al.'s (1995) model was a visible shift away from the traditional view of soil profiles in pedology to a statistical

representation of soil layers defined more commonly among geomorphologists (a theoretical shift from vertical to horizontal soil distribution). This new approach attributed environmental factors as a leading driver of surface and subsurface soil variability. Gessler et al. (1995) promoted a nonrandom soil sampling strategy in areas characterized by landform variability. This provided a uniform means of statistically predicting soil distribution in areas without variable topography. Both Gessler et al. (1995) and McBratney et al. (2003) called for a scientific rather than subjective means of defining soil series and distribution. New digital soil mapping techniques heed this recommendation, but utilize remote sensing methods to reduce field sampling.

Remote sensing (see AIRBORNE REMOTE SENSING) in soil survey has increased in applicability over the last decade. Remote sensing has been employed to reduce the confounding problems of scale and generalization outlined by Holliday (2004). Specifically, Mulder et al. (2011) argues that the most appropriate application of remote sensing in soil survey is to improve incomplete or inaccurate soil distribution data and integrate regional soil surveys into global soil databases. Remote sensing can accurately determine soil attributes such as mineralogy, texture, and organic carbon. Optical spectroscopy is the most useful remote sensing technology for soil surveying purposes. However, Mulder et al. (2011) argues that remote sensing of soils still lacks a cohesive methodology to incorporate statistical interpolation holistically with measurements of soil attributes.

Remotely sensed soil data is being employed in the creation of digital soil maps, which can more accurately define the boundaries between soil classes based upon quantitative rather than qualitative analyses of soil attributes (McBratney et al. 2003). Spectral reflectance of soils and other environmental features are being employed in order to create global maps of soil distribution without having to rectify scaling issues. Digital soil maps are being used to create predictive soil models, which help to elucidate the complex interactions between soils and their biophysical and biogeochemical functions (Scull et al. 2003). Scull et al. (2003) argued that these new predictive models have greater implications for the field of soil science, potentially informing new insights

into the role of soil formation processes in spatial soil distribution. However, the most profound contribution of predictive soil maps and digital soil maps more generally is their ability to use raster grid networks to display spatial soil variation more accurately than choropleth maps.

New methods in soil survey and mapping represent advancements in analyzing spatial variability in soil series using remote sensing techniques, and in analyzing subsurface variability using reflectance spectroscopy (Demattê and da Silva Terra 2014). Brevik et al. (2016) calls for soil survey and mapping to better integrate remote sensing, geographical information systems, and on-site geophysical information in the future, in order to better predict soil distribution and validate current soil-landscape models. Brevik et al. (2016) argues that soil survey is becoming increasingly useful in helping to answer questions regarding land-use planning, environmental concerns, energy security, food security, water security, and human health. Soil survey and mapping was once the domain of soil science research, but it is becoming increasingly important to the interdisciplinary analysis of the environmental conditions affecting the lived experiences of past and contemporary populations.

Sonar and Sidescan Sonar

PANAGIOTIS GKIONIS and GEORGE PAPATHEODOROU

University of Patras, Greece

Sonar technology for maritime archaeology

Sound navigation and ranging (sonar) systems have been increasingly used in support of maritime archaeology since the 1960s. Their operation is based on the principles of underwater sound propagation and the concept of acoustic remote sensing. With their use, physical properties of underwater features of archaeological interest can be recorded from a distance by their interaction with sonar-generated acoustic waves. The sidescan sonar has been the most commonly used marine geophysical instrument in maritime archaeology, and it still remains a significant tool for seafloor mapping, due to its portability, ease of deployment, and low-cost availability.

Sonar systems and acoustic remote-sensing techniques found wide acceptance among scientists, researchers and engineers by reason of efficient propagation of acoustic waves in the sea. Particularly, sonar systems found applications in maritime archaeology from the early years of their commercial availability, around the 1960s, leaving behind some disadvantages of diving operations. With the use of sonar, large sea areas can be explored rapidly and deep-water investigations can be conducted beyond the depth or duration limitations of scuba diving. Water turbidity, currents, adverse environmental conditions, and shipping traffic can all restrict diving operations, but can little affect acoustic remote-sensing methods. Besides, using sub-bottom profiling sonars, a non-invasive investigation beneath the seafloor is possible. Beyond the use of sonar for detection of underwater features of archaeological interest, sonar imaging techniques provide information

about natural processes that have governed the underwater environment through the millennia. Archaeologists can then reconstruct sites and better understand their archaeological potential, the conditions of historical events at sea, and the interactions between the environment, human activities, and the archaeological material. Therefore, sonar data can help the archaeological site management through the prediction of site evolution. Nonetheless, the use of sonar has certain limitations related to cost, logistical issues, time constraints for availability of quality-controlled data, and their specifications against the survey objectives. Furthermore, different kinds of sonars provide data for specific applications, and process acoustic signals affected by unpredictable phenomena, like tides and water-column temperature gradients, that need to be accurately compensated for. This has to be done by qualified surveyors who also have to plan the fieldwork strategy and determine the sonar recording parameters. Therefore, the quality of the sonar outcome is largely related to the surveyor's level of competence, the survey specifications followed, and understanding of the archaeologists' objectives.

A full interpretation of sonar records requires expertise in the fields of marine geophysics, hydrography, marine geology, and underwater acoustics. However, a basic understanding is feasible, provided that basic knowledge of sound propagation and system operation exists. The active sonar systems accommodate underwater transducers emitting acoustic pulses in the sea in the form of acoustic waves or pressure fronts. The frequency of operation of a sonar system is equal to the number of pressure fronts transmitted per unit time. The transmitted acoustic signals interact with the water volume and features in the water column, as well as with seabed features, and are refracted, spread, scattered, attenuated and reflected in different directions. Only a portion of the signals return back to the transducers as echo or backscatter. The returned acoustic energy is then converted to electric signals, which are processed and rendered graphically in a display such that the variability of the returned acoustic energy represents the variability of physical

DOI: 10.1002/9781119188230.saseas0541

properties of the seabed. From the two-way travel time of acoustic signals, quantitative results can be achieved, often related to seafloor bathymetry and the georeference of features. Passive sonars only receive signals radiated by underwater sources, hence only provide underwater communication and telemetry solutions. A full presentation of the principles of underwater sound can be found in Urlick (1983).

The sidescan sonar

Sidescan sonars are widely used in underwater archaeology for imaging objects of archaeological interest lying on the seafloor and for mapping seafloor geomorphological features that improve the site understanding. Some of their common applications include mapping of submerged landscapes, detection and visualization of modern and ancient shipwrecks, artifacts, and features related to human activities. They also provide information about the seafloor geomorphology and the texture of the sediments covering the seafloor. This kind of information is useful for assessing the impact of underwater natural processes and of human activities on the underwater cultural resources, and hence for assessing the site evolution.

A sidescan sonar configured to be deployed from a surface vessel typically comprises a transceiver processing unit, a towfish where a pair of transducers are housed, and a tow cable for underwater tow and for sound signal and data acquisition control (see Figure 1). The towfish can either be towed behind the vessel or pole-mounted. Sonar control can be achieved through a workstation linked with the topside processor. Since all explored features have to be precisely positioned, a marine GNSS (see GPS (GLOBAL POSITIONING SYSTEM)) has to feed the system with positional data.

The towfish transducers emit acoustic pulses in the form of beams, each side of the towfish. These acoustic signals are partially absorbed in the seabed and partially scattered or reflected off the seafloor and from objects lying over the seafloor. Only a small amount of the signals finally scatter back to the transducers, and this contributes to the imaging process. The side-

scan beams are formed wide across-track and narrow along-track (see Figure 2a), so the sonar senses the backscatter from a narrow strip of the seafloor, except for the nadir sonar sector.

The sonar beam angle (thereafter the along-track width of the ensonified stripe) dictates the along-track resolution of the sonar which corresponds to the sonar ability to resolve between two objects in the along-track direction. The across-track resolution depends principally on the electroacoustic specifications of the pulse length (Quinn et al. 2005) and corresponds to the sonar ability to resolve between two objects in the across-track direction. The forward movement of the boat leads to a full insonification of the seafloor each side of the boat along its course and within the sonar horizontal range, except for the nadir sector. The intensity of the received acoustic backscatter depends on the angle of incidence of the acoustic signal to the seafloor and the physical properties of the seafloor. Thus, acoustic backscatter provides information about the variability of the seafloor slope, morphology, roughness, as well as the variability of material and roughness of objects over the seafloor. On a sonar record, rocky seafloor is showing higher backscatter than fine-grained sediments, an upslope seafloor is showing higher backscatter than a downslope, artifacts made of steel are showing higher backscatter than softer material, and areas of the seafloor not ensonified due to sonar geometry and seafloor morphology are represented as acoustic shadows. Acoustic shadows often help the interpretation of records in three dimensions rather than masking information. It is up to the sonar data processor to choose to represent the relatively high backscatter with either relatively light or dark tones. Accordingly, shadows are represented with either black or white color. An insight into the sidescan sonar theory of operation and record interpretation can be found in Blondel (2009).

Figure 2b is a snapshot from a sidescan sonar display, showing raw data from the sonar's port beam. The dashed line along the right edge of the display indicates the towfish past-track over the seafloor with its latest position top right. The white vertical strip parallel to the dashed line assumes no data and corresponds to the travel time of pulses through the water column.

The sonar record highlights scattered archaeological material and the seafloor sediment distribution. Inset in the sonar imagery is the photographic depiction of a recorded cannon. It is evident that limitations in object identification exist, and these are largely related to sonar specifications and geometry. High-frequency systems (400–900 kHz) of short pulse width may provide high-resolution outcomes suitable not only for object detection but also for object identification, but only in short ranges. Figure 3 shows the sidescan record of an ancient shipwreck that has been ensonified by various frequency pulses, and thus exhibiting different resolutions.

In the sidescan sonar display, the y axis represents the track of the towfish over the seabed, while the x axis represents the two-way travel time of the acoustic pulse. The raw sidescan data in both x and y axes is not to scale; the vessel's speed is variable and the travel time of acoustic pulses does not directly represent distance over the seafloor. Archaeologists need to analyze the sonar outcomes scaled and often projected onto maps, where they can correlate the recorded features with findings from other surveys. Also, they often need to study the regional imagery of a site and the spatial distribution of findings. To that end, sidescan data processing is essential and corrections need to be applied to the sonar image. Then data from single lines can be mosaiced and georeferenced, so that ground coordinates

are assigned to displayed features in regional imagery.

Sonar advancements

The need for high-resolution mapping in three dimensions (3D) and exploration of deep-sea energy resources has driven a wealth of sonar technological and methodological advancements. Underwater archaeology enjoys their benefits, deriving a better understanding of trade through the open seas in the ancient world. Submersible technology allows scientists to operate sonars onboard autonomous underwater vehicles (AUVs) or remotely operated vehicles (ROVs) close to the ocean seafloor, and thus acquire high-resolution data transmitting high-frequency signals in that short range. Furthermore, the application of parametric and chirp technology in low-frequency signal generation and processing has helped the improvement of resolution and signal penetration of sub-bottom profiling systems. Signals from these systems penetrate the seabed up to a limiting depth and reflect from the various sedimentological, geological or artificial boundaries, providing high-resolution stratigraphic profiling. The development of 3D sub-bottom profilers allows the 3D reconstruction of buried shipwrecks and site paleogeography. Synthetic aperture signal

Figure 3 Sidescan sonar records showing an ancient shipwreck (assemblage of amphoras), resting on the seafloor, acquired at different frequencies (100, 400, and 900 kHz). Higher frequencies provide higher resolution. High backscatter, which is attributed to hard substrate, is presented by light tones on records. Low backscatter (soft substrate) is presented by dark tones (modified from Geraga et al. 2015). sw, shipwreck; ro, outcropping rock; as, acoustic shadow.

processing is another advanced technique based on the concept of virtually long transducers for achieving high-resolution imagery regardless of the sonar range.

The most significant advance in sonar technology has been the development of swath bathymetry systems. Two types of such systems exist: multibeam echosounders, which are a direct development of single-beam spot-depth echosounders, and the interferometric sonars, which are a direct development of sidescan sonars. Both are either mounted on a survey vessel or deployed on AUVs/ROVs, providing bathymetric information for a strip of the seafloor as long as up to 12 times the water depth. As the vessel moves forward, they can fully ensonify an area providing a point-cloud of depth soundings so dense that scientists use it to create a 3D model of the seafloor and of objects lying upon it, after proper processing of the acquired data. Backscatter information is also an option, so sidescan imagery can be generated and directly related to the third dimension. Swath bathymetry systems are used for detection of features of archaeological interest and for gaining a better understanding of the dominant natural processes of a site.

The great potential of sonar technology in support of underwater archaeology can be revealed through the synthesis of outcomes from a combination of applied sonar techniques. Geographical information systems (GIS) are digital platforms where sonar outcomes can be visualized, fused and correlated in four dimensions (including time) for spatial and temporal analysis of findings.

Synthetic Aperture Radar

BRUCE CHAPMAN

Jet Propulsion Laboratory, California Institute of Technology, USA

Since the 1970s, synthetic aperture radar (SAR) data have been used in various ways in the study of archaeological sites. SAR transmits a series of microwave pulses towards the desired ground image swath, and then coherently receives the backscattered echoes. The returned signal data are then processed into high-resolution imagery. Some of the advantages of SAR, such as all-weather imaging, foliage and dry sand penetration, topographic and survey mapping, sensitivity to man-made features, and disturbance detection, have been employed to further archaeological studies.

Twenty-seven years after Carl Wiley at Goodyear Aircraft Company invented SAR, the first civilian spaceborne SAR was launched into Earth's orbit onboard the ground-breaking NASA Seasat satellite in 1978. This L-band (23.5 cm wavelength) SAR demonstrated many of the capabilities that have since led to the launch of over 20 civilian spaceborne SARs, such as ocean observations, geological mapping, and dry surface penetration; and also the use of interferometric SAR for mapping surface deformations (Elachi 1980; Gabriel, Goldstein, and Zebker 1989). An airborne prototype for the Seasat SAR (and other NASA SAR missions such as the Venus Magellan Radar) flew onboard the NASA Ames CV-990 Airborne Laboratory during the 1970s and 1980s, and conducted the first attempted archaeological application of SAR by overflying northern Belize and virtually all of the Petén region of Guatemala (Adams, Brown, and Culbert 1981). The objective was to investigate whether foliage penetration would enable mapping of ancient roads, causeways, and other manmade structures. While the results were not conclusive, these same objectives would guide many future archaeological experiments with SAR.

In 1981, the Shuttle Imaging Radar-A (SIR-A) flew on the second flight of the NASA Space Shuttle Columbia for a short duration (only two days in orbit) technology demonstration. The L-band SAR images of the Egyptian Sahara seemed to indicate a terrain carved by running water; however, the surface landscape was dominated by windblown sand. These SAR images were found to have revealed previously unknown buried valleys, geological structures, and possible Stone Age occupation sites. The locations of these drainage networks provided a geological explanation for the locations of human habitation (McCauley et al. 1982). Indeed, recent work shows repeated human occupations of the Sahara during wetter phases of the climate.

Figure 1 shows a SIR-A image overlaid upon an optical Landsat MSS image and illustrates the starkly different appearance of SAR and optical imagery under these conditions. Field measurements showed that the “radar river” features were covered by a thin layer of dry sand (depths sometimes greater than 1 m) (Elachi, Roth, and Schaber 1984). SAR imagery from subsequent spaceborne instruments such as the NASA SIR-C SAR, the Japan Aerospace Exploration Agency (JAXA) JERS-1, and JAXA ALOS PAL-SAR SAR instruments, further identified these paleodrainage channels. Imagery from higher frequency SAR systems such as the Canadian Space Agency (CSA) RADARSAT-1 (a C-band, 5.5 cm wavelength SAR instrument) was also found to be sensitive to the presence of these sand-covered drainage channels. The discovery of the locations and the subsequent dating of these paleodrainage systems have a clear value for understanding past environments and climates of northern Africa, including their impact on human habitation.

Following the opportunistic polarimetric and multifrequency SAR imaging of the Angkor Wat site in Cambodia by SIR-C in 1994, a more extensive imaging campaign was conducted by a NASA airborne SAR called AirSAR operating on NASA's DC-8 flying laboratory in 1996 and 2000. Operating in a topography mapping mode, where data from two antennas are interfered to

Figure 1 This figure shows a SIR-A image of the western desert of Egypt laid upon a Landsat MSS image. The VNIR Landsat image shows the present-day surface sand cover, while the radar image shows a fluvial landscape from wetter climatic episodes in the Sahara. Upper left inset shows from the ground the appearance of a “radar river”. Note jeep on riverbank for scale. Lower right inset shows typical artifacts collected. SIR-A image swath width is 50 km.

estimate ground elevations, the data revealed new structures and significantly enhanced regional understanding (see Figure 2) (Moore, Freeman, and Hensley 2007). This mapping campaign showed that highly accurate and fine-resolution topography data could be very useful for the identification of manmade structures, even in the presence of confounding topography from vegetation and other natural features. It was soon discovered that airborne laser scanning technology (lidar) could be as or more effective than SAR at mapping microtopographic features (see AIRBORNE LASER SCANNING AND LIDAR). This technique has since revolutionized the use of remote sensing data in archaeology.

Fully polarimetric, multifrequency observations by SAR continue to be used in other investigations, such as developing predictive models for potential site locations (Comer and Blom 2007), and in continued work to investigate whether foliage penetration would enable mapping of ancient roads, causeways, and other manmade structures. SAR has also been used for producing large-scale archaeological surveys. The advantage of using SAR is its sensitivity to certain geological features such as lineaments and sub-pixel manmade features.

Very high resolution (<1 m) observations are possible from space using X-band (3.1 cm wavelength) SAR systems such as TerraSAR-X and COSMO SkyMed satellites. Using the TerraSAR-X Staring Spotlight mode, Balz et al. (2015) were able to identify small grave mounds in China. One of the advantages of this type of high-resolution SAR imagery over readily available high-resolution optical imagery is its inherent all-weather imaging capability.

During an airborne campaign to South America in 2013 and 2015 by NASA’s UAVSAR, an L-band and fully polarimetric airborne SAR, data were collected over The Lines and Geoglyphs of Nasca and Pampas de Jumana World Heritage Site in Peru. Geoglyphs, created by the Nasca people by moving small stones to form geometric as well as biomorphic figures, are found across a wide expanse within in this dry desert landscape. Since SAR is sensitive to the scattering behavior of these small stones, some of the geoglyphs are readily discernable in SAR imagery if the resolution is sufficiently high. Also, since there is little vegetation or weather affecting this area, the magnitude of the interferometric coherence from interferometric SAR (InSAR) was found to be an indicator of vehicular and even foot traffic within this fragile protected zone. Figure 3 illustrates what this type of data looks like, and shows three unpaved roads within the protected zone of the Nasca World Heritage Site that have been driven upon between the time of the observations (March 2013 to March 2015). Power lines are in the upper right-hand portion of the image, where the decorrelation stands out due to the movement of the power lines between observations. This result demonstrates the value of interferometric SAR data in some areas, for the protection and

Figure 3 Calibrated magnitude of the coherence image from UAVSAR overlaid in Google Earth. Black corresponds to decorrelation, typically due to disturbance between the two observations (March 2013 to March 2015), while grey and light grey correspond to areas with minimal decorrelation. The horizontal line in the center of the image indicates 100 m. Source: Chapman et al. (2015), UAVSAR imagery. Courtesy NASA/JPL-Caltech.

management of sensitive archaeological sites (Chapman et al. 2015).

In the future, freely available and widely collected data from the ESA Sentinel-1 SAR satellites and the NASA-ISRO synthetic aperture radar will enable widespread use of SAR data for many endeavors, including those in archaeology.

Terrestrial Excavation

STEVE ROSKAMS

University of York, UK

If excavation in general is defined as the exposure and removal of deposits, then terrestrial excavation in archaeology can be seen as carrying out this process systematically on land to generate data relevant to the interests of the discipline, that is, the study of past human societies and their environments. All such excavation involves removing the layers and features of a site in the reverse order to which they were laid down, in the process creating a range of descriptive, spatial, and chronological data. Yet this work can be approached in a variety of ways, depending on its extent and form (open area versus boxes versus pits), the definition of deposits (by individual contexts versus the planum/schnitt method), and institutional setting (rescue/salvage work ahead of modern development versus research projects investigating otherwise unthreatened sites). Some of this diversity is explored below.

Today, excavation is mostly considered the principal way in which archaeologists gather evidence. Yet, historically, the discipline started by *collecting* material culture, first to satisfy the aesthetic needs of social elites, notably within Europe, then, later, to elucidate social development, often as part of a project to create identities within emerging nation states: to give them a sense of “their” past.

This collection phase led to the plotting of monuments: *mapping*. Investigation of their distribution threw up gaps across the landscape: Were these significant or simply a product of buried or destroyed features? From here, it was only a short step to *excavating* to check patterning, in the process gathering finds to add to existing collections. The move from collecting to mapping to excavating happened at different times in different parts of the world, but the general sequence is almost ubiquitous. Understandably, the actual form of intervention varied greatly: for

example, wall chasing to confirm building plan form, or digging, often fairly randomly, into the centers of mounds to find burials and recover associated grave goods.

In order to play its growing role in charting social development, excavation needed to move beyond the notion of a past constructed in terms of individual monuments, frozen in time, to focus on generating evidence concerned with sequences of change. This, in turn, meant attending to any archaeological stratigraphy revealed in the course of such work. In western Europe, this approach was increasingly evident in the course of the nineteenth century, for example, with Pitt-Rivers (Bowden 1991), but had its clearest expression in the work of Sir Mortimer Wheeler in the twentieth century (Wheeler 1954) and his promotion of box excavation. This attempted to reconcile the needs for vertical control of sequence, as recorded in section drawings of baulks (the unexcavated stratigraphy between boxes), with the requirement to elucidate plan form. Under the influence of colonial rule, this approach spread to different parts of the world, and is still used on many archaeological sites today.

Box trenches were, however, poorly suited to recording non-rectangular features and buildings: Baulks sometimes obscured stratigraphic relationships, while, within even quite small excavated areas, not all of the layers reached their sides, to then appear in the section drawings. Thus, “open area” excavation techniques were developed, at first, unsurprisingly, on sites with irregularly distributed or asymmetrically positioned features, in particular in Scandinavia under the influence of Axel Steensberg, then spread further, for example by Gerhart Bersu. This change in technique also involved an advance in the complex detail involved in recording plan form *in extensio*, for example with the use of color drawings, now extended through the use of the global positioning system (GPS) in conjunction with digital photography.

Today, there is no one dominant approach worldwide (Carver 2011, Figure 4.8): In some regions, mostly western Europe, “open area”

techniques prevail; across much of southern and eastern Asia, “box excavation” is more prominent; and in the Americas and Australasia, smaller “pit excavation” prevails. The differences seem to relate to the character of the sites under investigation and the research agendas being applied to them.

Whatever the extent of exposure of archaeological strata in each case, however, these approaches involve attempting to define the limits of each distinct deposit, then recording and removing it. In contrast, across eastern Europe and northern Asia, most sites are excavated in arbitrary levels, the so-called *planum* or *schnitt* method. This is best deployed where deposit boundaries are indistinct, and thus stratigraphic divisions have to be imposed. Such sites are clearly more common in the latter regions (or a mixture of systems is often needed: Hester, Shafer, and Feder 1997, 88; Carver 2011, Figure 1.1).

Excavation practice is not only affected by site characteristics but also by developments beyond archaeology. This includes ideological changes such as the rise of science and Darwinist perspectives, as seen in Lyell’s *Principles of Geology* (1830–33) which, ultimately, had a profound impact on the recording of archaeological sequence. These theoretical advances were, in turn, underpinned by real-world concerns, for example, for Lyell, by the scale of nineteenth-century geological exposures in quarries, canals, and railway cuttings (not to mention light detection and ranging (LiDAR), GPS, carbon dating, and dendrochronology since then, all developed outside our discipline but having considerable significance within it).

Yet it could be argued that social and organizational factors, not ideas or techniques, have had the most lasting impact on excavation work: Pitt-Rivers, a British aristocrat/soldier with the land and resources to carry out his ground-breaking fieldwork in the United Kingdom; and Schliemann, a German industrialist with the money to finance his expeditions and the colonial contacts to ensure they were permitted. These are parochial examples, but the organizational context of excavation has taken on a global dimension from the mid-twentieth century. Up to that point, much excavation was carried out for reasons of research, whether by interested

parties in local groups or governmental institutions such as museums and universities. From the late-1960s, following the long boom in the world economy, threats to the archaeological resource at unprecedented levels were recognized.

These pressures were evident in both rural contexts, where extraction of aggregates and minerals, creation of infrastructure, afforestation/deforestation, and mechanized ploughing impacted increasingly on once “safe” sites, and urban settings, especially historic towns, which saw expansion, high-rise developments, and new transport systems. Their scale and severity required an equally large-scale response from the archaeological community: The need to rescue this heritage by creating an excavation “archive” in place of the site itself was recognized and innovative methods developed in many countries to cater for the variety of new, and often difficult or dangerous, working conditions. Perhaps the most significant result, however, was the creation of a new breed: the full-time, professional excavator.

All excavation involves splitting a site into its component parts (stratigraphic units), each with physical, spatial, and chronological properties. Teams of paid, professional staff created a need to systematize the process. This resulted in a greater emphasis on proforma sheets to hold descriptive information, set rules for gathering spatial data in plan and section drawings, and more orderly ways of holding stratigraphic evidence, exemplified by the Harris–Winchester matrix (Harris 1989).

Recording systems today can be divided between those that are hierarchical, for example recording layers and features, and those that employ “flatter” single-context systems. The stratigraphic units they encounter are mostly deposits, using proformas to record color, composition (particle size and inclusions), compaction, and thickness (their extent usually recorded in the form of a plan). Other proforma are used for cut features, recording orientation, shape, depth, nature of sides and base, and so forth, while some projects will employ sheets designed for masonry or timber features and human burials.

The creation of a fieldwork profession, in response to the impact of modern development, brought excavation solidly within the planning process. In recent decades, this has meant greater

integration with environmental impact procedures and associated legislation, reinforcing the need for early consultation to ensure integration of the roles of the developer (with or without the use of their own archaeological consultant), the curator/cultural resource manager, and the contractor/commercial excavation company.

The focus on assessing impact necessarily places increased emphasis the process of reconnaissance (notably “desk-top” studies and aerial photographic survey), and then ground-based evaluation (whether by nondestructive techniques such as geophysics and surface collection, or by more destructive techniques such as shovel testing, bore holes, and test pits). The objective here, in essence, is to consolidate knowledge of the development area to guide future strategy, perhaps most usefully done when all information is combined in the form of a deposit model (Carver 2011, 121).

These stages—reconnaissance/evaluation/strategy (whether or not they use this terminology)—are encountered in many countries today, albeit stretched over different timescales and emphases. What then happens in terms of excavation fieldwork depends, however, on heritage policy. Some countries use the process to identify their most important sites and then excavate them. Others, and this is more closely aligned with the notion of assessing impact upon a fragile, irreplaceable archaeological resource, see the end result as in-situ preservation of those same “important” sites, and hence aim to generate a mitigation strategy.

Either way, if destructive excavation is agreed as acceptable, such work will require some generic preparations: site safety, spoil disposal, shoring, and so forth. It is also likely, and certainly desirable, for its implementation to pass through a cycle of defining a research agenda; modifying such in the light of reconnaissance and evaluation; and then defining sampling strategies and structured data gathering. Any project will also need to undertake specialist analyses post-excavation to allow interpretation and synthesis, followed by dissemination and archiving. A good excavation project will, almost certainly, end up posing more questions than it started with. Yet it will, hopefully, be in a position to articulate an augmented research agenda and say

how it might be best fulfilled: Research questions should drive the whole fieldwork process.

Any excavation will need financial provisions: Excavation is not only destructive, by definition, but also costly in time and resources (increasing use of digital recording systems may reduce such costs or, better still, free up excavators to spend more time on interpreting their evidence). Resourcing excavation projects varies considerably with national context. The original rescue/salvage excavation work from the 1960s onwards was mostly supported through state funding in various guises. In subsequent decades, under the twin influences of general neoliberal frameworks downplaying the role of state expenditure, and the “polluter (here the commercial developer) pays” principle embedded in most environmental impact systems, some countries have moved towards privatizing the profession. In this brave new world, excavation work is subject to the vagaries of the world economy, seen most obviously in the impact that the 2008 recession in western Europe and North America had on excavators’ employment (Schlanger and Aitchison 2010).

As a result of these changes, excavators today face a series of challenging questions, for example whether our ethical priority is to investigate or to preserve sites. Second, the influence of post-processualism within the discipline, aligned with the material way in which excavators encounter the past (Edgeworth 2006), questions how, and when, we should be interpreting excavated evidence: reflexively, “at the trowel’s edge” (Hodder 2000), or only after post-excavation analysis? Finally, and perhaps of greatest importance, the move towards professionalization noted above distanced the excavator from her/his audience. This dissociation from the community we serve has increased further with recent commercialization, creating mobile excavation companies with no set geographical area of interest. How might we cross that divide? And if commercial excavations are to remain research-driven, who should set that agenda and at what level: local, regional, national, or international?

Terrestrial Lidar

LORI D. COLLINS

University of South Florida, USA

Traditional methods of site survey for heritage preservationists and archaeologists are often time-consuming and involve the use of subjective techniques such as sketch and field drawings, drawings derived from images, and survey mapping using local systems of reference that lack global coordinates. Documentation of features and objects within a site or structure is also often performed using subjective or time-consuming dimensional recording strategies, including hand-drawn and measured renderings or computer-aided drawings (CAD) that rely on hand measurements, and require physical access to the object or area being documented. Terrestrial lidar survey and laser scanning applications, particularly when integrated with other forms of spatial survey and documentation, offer new potentials for more rapid, robust, accurate, and representational recording of archaeological and heritage phenomena.

Aerial lidar or aerial laser scanning (ALS) is perhaps more broadly applied and understood in the heritage and archaeological sectors than is terrestrial lidar or terrestrial laser scanning (TLS). Several recent exciting applications of ALS, including archaeological prospection of Maya sites in Belize and at the site of Angkor Wat in Cambodia, are producing results that provide broader landscape and spatial coverage capabilities. TLS affords a higher degree of resolution and point density than ALS, and is used in heritage to record phenomena at a closer scale. TLS offers a rapid and highly accurate means of documenting complex archaeological sites and objects in 3D, producing a quantifiable output. Like ALS, TLS is a form of active remote sensing survey that utilizes light pulses and their reflectance to measure distance. TLS data can be used to provide high-resolution terrain and surface details that are representative of the object or environment.

This form of survey is often used in a multisensor approach, with photogrammetry and imaging, global positioning system (GPS) survey, and ALS strategies often performed together.

TLS survey can be performed using static, mobile, or handheld platforms, and can provide a means of acquiring direct measurement across complex or difficult-to-access locales. Tripod-based survey using TLS is used in heritage and archaeological studies to provide highly accurate dimensional recording of sites, features, and objects of interest. Instruments used in the static tripod survey approach range from centimeter accuracy at the long-range landscape scale, to millimeter accuracy, with surveys of built structures and historic resources generally falling in the 1–2 millimeter accuracy tolerance. Instrument types in this range include time-of-flight (TOF) or pulse-based scanners, and phase shift scanners, with differences in the way that distance measurements are resolved based on the way that light is sent out from the instrument. In general terms, phase-based scanners are fast and can acquire data at a rate upwards of a million points per second, but generally do not penetrate as far as a TOF laser. Phase-based scanners can be more accurate, but have limitations on distance, being best suited for documentation out to 300 meters. New technologies are blurring the distance distinctions, with phase and TOF laser scanners now generally able to be used in similar environments out to several hundred meters depending on the instrument, but longer-range ground-based scanning out to kilometers is possible with certain TOF configurations. Preference for work flow and use with integrated surveying strategies are the most common reasons for instrument selection. Choice of TLS equipment also centers on data density requirements, data noise and clarity, ease of use, cost, and instrument weight and size. Trends in scanning instruments have been moving towards smaller, more portable and easy to use options, with lower price points and integrated sensors such as high-resolution cameras, on-board computer interface and touch screens,

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0575

and GPS possibilities. Many of the static or tripod instrument options are able to be adapted to mobile platforms, such as vehicle mounting, and more recently smaller scanners are being utilized with unmanned aerial vehicle (UAV) drone device deployment.

Data generated from both static and mobile applications provide precise X, Y, and Z measurements in dense point clouds that represent the external surface of a structure, terrain, or object, and can also contain information regarding surface reflectivity and color when used with integrated photography and imaging systems. TLS phase shift and TOF instruments are spherical scanners, and can collect measurement data and imagery in 360 degrees horizontally and 300 degrees vertically. Data are acquired rapidly, with survey positions established to allow for movement of the scanner to a prescribed distance and acquiring targeted commonality between scan locations.

Tripod or static survey methods often involve the use of targets or markers that provide reference for precise registration of the data. Artificial references using sphere and target configurations are often specific to the hardware and software choice, and are used as part of a survey kit to provide a means of scan alignment and registration. Alignment can also be obtained based on 3D image matching procedures that examine natural references, such as planes, rectangles, and corner points, but these methods often require more overlap commonality between scans and can be less accurate than using artificial references or assigned coordinates. Target locations can be shot-in using GPS or total station methods, with coordinate control applied to the scan data for higher accuracy and match (Kinney 2017).

Photographs acquired either internal or external to the scanner are used to provide color and texture, allowing for a realistic depiction of the heritage or archaeological phenomenon (Remondino and Campana 2014). Many scanners have on-board cameras that also provide spherical image capture in 360 degrees, allowing for immersive virtual data exploration.

Taking point-based measurements into a surface meshing software allows for solid surface development, producing highly detailed rendered models. Depending on software preference and post-processing pipeline, point cloud or solid

surface models can be used to create measured sections and drawings, and these data derivatives are becoming more automated, with 3D software packages offering valuable applications for architectural and structural engineering specialists in the heritage sector. Visualizations, animations, computer-aided drawings (CAD), and model renders have broader impact value for heritage tourism and interpretation, and are increasingly being shared through global 3D social media platforms, and through the use of embeddable viewers online.

Hand-held and portable laser scanning is generally available for more close range and higher precision needs. These types of scanners include short-range triangulation instruments and projected or structured light instruments. Laser-based scanners capture an object's shape by projecting a laser line or multiple lines onto an object and then detecting the reflection using single or multiple sensors. Using triangulation, the locations of points are determined by forming triangles between them, allowing these scanners to capture a 3D shape accurately (Stylianidis and Remondino 2016). Point cloud areas or patches collected from these scanners can then be merged or stitched manually, or are captured using real-time registration utilizing commonality in the positions recorded (van Dijk et al. 2016). These merged or solid surface data can then be further refined using 3D modeling software. Triangulation scanners are a good choice for archaeological documentation that requires high precision and accuracy for objects ranging in size from hand-held to approximately the size of a car. These types of scanners are less sensitive to lighting conditions and can be more portable and able to scan tough surfaces such as dark or shiny objects. Examples of archaeological applications using triangulation scanners include museum collection documentation, and digitization of sculptures and monuments (Cordova Tello et al. 2016; Doering and Collins 2010; van Dijk et al. 2016).

Structured light scanning instruments are increasingly becoming more widely used in archaeological field methods, but care must be taken for environmental conditions, such as lighting and appropriateness of surface and area that are being recorded. Structured light instruments offer high geometrical accuracy, and are most appropriately used in controlled environmental

settings, such as in museums and laboratory settings (Kersten et al. 2016). Trade-offs with these types of scanners include the size and type of materials that can be captured, and the necessity for control over environmental conditions, such as lighting. Many commercially available structured light and triangulation scanners now come in affordable and highly portable size and weight configurations, with on-board computing integration and options for battery powering, which makes these instruments a reasonable addition to the archaeological digital field kit.

There are numerous examples of successful application of TLS survey methods in the archaeological and heritage sector. These types of tools have been used to record complex terrains, and perform analyses relating to land formation and use processes, such as erosion, and change detection. TOF and phase-based spherical scanners are suited for the examination of landscape and architectural built environments. TLS methods can provide detailed terrain and structural analyses and understanding, with point clouds used to produce digital surface models (DSM), contour maps, 3D CAD, elevations, profiles, volumes, and section details.

TLS is also proving a useful survey strategy in rescue and disaster response scenarios, with examples of rapid, non-contact survey needs in areas where heritage and archaeological sites are imperiled or threatened by natural and cultural change, or activities such as terrorism and war (Greenop and Landorf 2017). TLS surveys in difficult-to-access cave and karst environments are being conducted to map complex features, to conduct pattern and condition assessment, and to perform monitoring for erosion and weathering processes. Geophysical survey techniques in these environments, such as ground-penetrating radar (GPR) survey, can be conducted along with TLS to provide above-surface terrain characteristics that relate to the below-surface anomalies.

TLS, along with other forms of portable structured light and triangulation laser scanning, are also valuable in the digitization of monuments, rock art, and carved surfaces (Doering and Collins 2010). Heritage management, museums, and tourism sectors also benefit from these survey and documentation strategies, with TLS increasingly used along with traditional recording methods such as photography and

measured drawings. New lower-cost scanners and photogrammetric and reality capture tools are being incorporated into the archaeological kit (Davis et al. 2017); however, caution in terms of precision or repeatability of measurements with lower-cost devices and modeling is needed, along with considerations for trueness and accuracy of representation, and resolution.

Other heritage and archaeological applications with TLS survey include recording archaeological context, and in situ human remains, artifacts, and features. These types of applications benefit from the rapid, accurate, and non-contact means of survey, the potential for lessening disturbance of remains and artifacts, and benefiting regulatory and legal requirements such as the Native American Graves Protection and Repatriation Act (NAGPRA).

Conservation techniques and applications are also increasingly using 3D and laser scanning data, with rapid prototyping and 3D printing techniques benefiting from the detailed and representational models that emerge from laser scanning. New opportunities for sharing and broad dissemination of 3D models are being used with heritage objects and artifacts that have been laser-scanned. Online sharing and virtual model representation has the potential to increase collaboration and make archaeology more accessible.

The pace of technological innovation in the area of laser scanning for archaeology and heritage is fast, and with any new approach, guidance and caution is needed. Considerations are needed not only for best practices, but for ethical implications such as copyright, permissions, and distribution practices. Instrument selection and approach includes aspects of cost, portability, technical expertise, and appropriateness of scale. Thought must also be given to object surface characteristics such as shine and reflectivity, which can limit scanning results. Environmental aspects such as intensity of light, and exposure to elements such as dust, cold, or heat can also be critical factors in instrument selection and techniques. Understanding the final purpose for the data to be collected can greatly assist with instrument selection, method, and approach needed. Also critical is the production of data with archival stability, with preference for file types that are neutral and flexible in terms of software and operating system.

Thermography

AUTUMN C. COOL

Independent Consulting Archaeologist, USA

Aerial thermography is a geophysical survey method in which thermal infrared radiation is recorded to show the distribution of temperature across a landscape. In archaeological contexts, anthropogenic features and their surrounding soil matrices often absorb and reradiate heat at different rates, causing features to appear as anomalies in thermographic images. Consequently, these images, called thermograms, may be used as maps which plot the location of subsurface archaeological features.

Archaeologists have been benefiting from the indirect collection of thermal data throughout the last century. The patterns created by unevenly melting snow form a sort of low-tech thermogram of a landscape. If archaeological sites are present, these patches may form regular patterns which trace the location of features. When seen from above, these snow marks can reveal a bird's-eye-view map of buried archaeological sites (see AERIAL PHOTOGRAPHY).

Regrettably, the fleeting phenomenon of snow marks is an unreliable tool for archaeological prospection. They are difficult to predict and appear only when conditions of climate, weather, and lighting align perfectly. Contemporary thermography, or thermal imaging, avoids these obstacles by filming surface temperature in the form of thermal infrared radiation directly with thermal cameras.

Thermal properties of materials

As in other forms of geophysical survey, thermography is used to detect archaeological features by looking for anomalies caused by unique behavior (see ELECTRICAL RESISTIVITY; GROUND-PENETRATING RADAR; and MAGNETOMETRY). The thermal behavior of materials is

determined by four thermodynamic properties: thermal conductivity, heat capacity, thermal inertia, and diffusivity. Most of our current knowledge of how these variables interact and manifest in archaeological contexts is attributable to the work of Périsset and Tabbagh (1981). While most archaeologists will not need complete command of the mathematical formulas they discuss to successfully employ thermography in their research, comprehension of these properties is beneficial in predicting when thermal imaging may be most productive, as well as in interpreting results.

The first thermodynamic property that may affect the behavior of archaeological materials is thermal conductivity. This describes the quantity of heat that a material is able to transport. Subterranean archaeological features will only be detectable via thermography if the soils they are buried in have sufficient thermal conductivity to allow a measurable amount of heat to penetrate to their depth.

The thermal conductivity of soils is dependent upon moisture, organic matter, density, and texture. In dry soil the spaces between particles are filled with low-conducting air, which restricts heat transfer. As moisture content increases, air is replaced with water and overall conductivity improves. Similarly, dense soils have greater contact between particles and higher conductivity than loose or porous soils. However, thermal conductivity decreases as organic matter increases and as soil particle size decreases. As a result, sand has high thermal conductivity, followed by sandy loam, loam, and clay soils.

The second thermodynamic property is heat capacity. Heat capacity does not describe how hot or cold a material can get, but rather how much thermal radiation must be consumed or lost to change the temperature of that material. For example, iron has low heat capacity, meaning it does not require much energy to become hot or cold. Water has high heat capacity, so it must absorb (or lose) a very large amount of thermal radiation before it undergoes a measurable temperature change.

Heat capacity can be described in two ways: specific heat and volumetric specific heat. The

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

© 2018 John Wiley & Sons, Inc. Published 2018 by John Wiley & Sons, Inc.

DOI: 10.1002/9781119188230.saseas0579

specific heat of a material is how much heat is necessary to increase the temperature of a unit *mass* of that material by 1 °K. The volumetric specific heat is the amount of heat necessary to increase the temperature of a unit *volume* by 1 °C. The conversion from specific heat to volumetric specific heat is calculated by multiplying the specific heat of a material by its density. In a heterogeneous soil matrix, the volumetric specific heat is the sum of the specific heats of all the soil components multiplied by the bulk density (Stanjek and Faßbinder 1995, 97). For archaeologists, volumetric specific heat is the more useful description of heat capacity as it takes into account both the density and the natural heterogeneity of soils, and because site size is usually described in terms of volume, not mass. However, rarely would an archaeological surveyor need to calculate this property precisely. It is often simpler and just as beneficial to focus instead on the third thermodynamic property.

The third thermodynamic property, thermal inertia, describes a material's resistance to changes in temperature. Thermal inertia I is represented by the equation

$$I = \sqrt{k \cdot C_v}$$

where C_v is volumetric specific heat and k is thermal conductivity. From this equation it can be seen that high thermal conductivity and/or high volumetric specific heat leads to high thermal inertia. In practice, the range of values for thermal conductivity is fairly small compared with the range of possible volumetric specific heat values, so thermal inertia is primarily determined by the heat capacity. A material with high heat capacity usually has high thermal inertia and vice versa. Due to its high heat capacity, water has high thermal inertia and is resistant to temperature changes. Because of the close association between these two properties and the relative ease with which thermal inertia is observed in the field, it is a very convenient proxy for heat capacity.

Possessing knowledge of the thermal inertias of the types of materials likely to be found in an archaeological site can be useful for estimating the potential strength of anomalies and in analyzing results. Like thermal conductivity, heat capacity and thermal inertia are predominantly affected by density and moisture content. Less dense or

porous soils tend to have low heat capacity and low thermal inertia. As density and/or moisture content increases, heat capacity and thermal inertia will increase (Stanjek and Faßbinder 1995, 97). Therefore, dry porous soils like sand will respond to temperature changes quickly, while moist, dense soils resist temperature change. Damp features such as filled ditches or wood objects will also resist temperature change, but low thermal inertia materials like metals will undergo more rapid and extreme changes in temperature.

The fourth thermodynamic property, diffusivity, describes how easily heat is conducted through a material. While thermal conductivity describes the quantity of heat that can be transported through a material, thermal diffusivity describes the rate at which temperature change occurs. As thermal radiation passes through a material, some will be absorbed, depending on that material's heat capacity. A material with low heat capacity will have high diffusivity, meaning that most heat travels through it quickly without being absorbed. In an archaeological site with high diffusivity soil, subterranean features will be exposed to thermal radiation more quickly, which will then allow them to experience temperature changes at rates dependent on their own thermodynamic properties, rather than being insulated and limited by the properties of the surrounding soil matrix.

Mathematically, diffusivity is the ratio of thermal conductivity to volumetric specific heat. It can be represented by the equation

$$\Gamma = k/C_v$$

where Γ is diffusivity, k is conductivity, and C_v is volumetric specific heat. The higher the thermal conductivity is relative to the heat capacity of a material, the higher the diffusivity will be. Finally, the relationships between all four thermodynamic properties can be described when the equation for thermal inertia I from above is rewritten as follows:

$$I = \sqrt{k \cdot C_v} = k/\sqrt{\Gamma}$$

Périsset and Tabbagh (1981) created several experiments to study the interaction of these thermodynamic properties. They constructed artificial archaeological features and designed a software program to analyze the thermal behavior of a feature embedded in a subsoil and then

covered with a superficial layer of a second soil type. From these experiments they were able to observe how the layers of soil around an archaeological feature will affect its thermal signature:

- As the superficial layer increases in thickness or decreases in diffusivity, thermal anomalies created by the feature will attenuate and their appearance will be delayed.
- As the superficial layer increases in conductivity, the thermal anomalies will attenuate, but will not be delayed.
- The superficial layer will have no effect upon the relative temperature of a thermal anomaly. Whether it appears as relatively warm or cold depends solely upon the properties of the feature and the surrounding subsoil.
- As thermal conductivity and diffusivity of the feature increase, thermal anomalies may be weaker as more heat is distributed into the surrounding soil and less is retained by the feature itself.
- Features located within low conductivity and low diffusivity subsoil will have the strongest thermal signatures.
- The potential strength of a thermal anomaly is determined by the thermal inertias of the feature and the subsoil. The greater the difference in thermal inertia, the greater the anomaly (Périsset and Tabbagh 1981).

Other characteristics of the surface layer can affect the outcome of a thermal survey. Heterogeneous surface soils are created by human activities, natural variations in bedrock and hydrology, and the presence of archaeological material. These inclusions can be helpful if they reflect the presence of archaeological features, such as mudbrick fragments brought to the surface by plowing. Conversely, they may create thermal noise which masks subsurface features. Variations in surface topography result in uneven surface exposure to thermal infrared radiation. If topography reflects subsurface features, such as a slight ridge over a buried wall, this impact may be positive. However, surface topography can also obscure anthropogenic thermal anomalies if it is unrelated to the presence of subterranean features (Scollar et al. 1990, 601).

Thermal cameras

Thermal infrared radiation has been traditionally recorded via satellites and scanning radiometers. However, thermal infrared satellite data have extremely low resolution (100 m in the case of Landsat 8), which is entirely unsuitable to most archaeological investigations (see SATELLITE HYPERSPECTRAL AND MULTISPECTRAL IMAGING). The scanning radiometer was an expensive, airplane-mounted system which required intensive image correction, georectification, and data processing. Predictably, aerial thermography was not a practical surveying method for most archaeologists. Only in the early twenty-first century has the deployment of aerial thermography become a feasible prospecting method for archaeologists, due to the concurrent development of compact thermal video cameras and drones (see DRONES).

The quality of data recorded by a thermal camera is determined by four types of resolution: temperature, spectral, radiometric, and spatial. Temperature resolution is the temperature increment the camera is capable of detecting. Spectral resolution describes which electromagnetic wavelengths are recorded. Thermal infrared radiation occupies the ranges 3–5 μm and 8–15 μm on the electromagnetic spectrum. Many thermal cameras record only within the 8- to 15- μm range. Radiometric resolution refers to the way data are encoded. Thermal cameras that record at 8-bit resolution are capable of representing temperatures with a maximum 256 different colors. Finally, spatial resolution refers to the real physical area each pixel represents and depends on the camera's proximity to the ground. In all cases, higher resolution is capable of offering more information; however, too much detail can become noisy and difficult to interpret.

Thermal video cameras usually record grayscale images, with black cells assigned to the coldest areas and white cells for the warmest. This is a relative scale that depends on the range of temperatures within each frame; that is to say, most thermal cameras do not consistently assign the same gray values to the same temperatures. This can make comparing thermograms problematic, as the same range of colors may be used to represent completely different temperature ranges.

Some cameras autocalibrate while recording, so temperature representation may not even be consistent frame to frame. The ideal thermal camera can be pre-calibrated to ensure consistent temperature representation. If such a camera is not available, this issue can be minimized by establishing ground control points with known temperatures to use as reference points for manually calibrating or resampling the data during processing.

Surveying

In aerial thermography, thermal cameras can be carried by drones, kites, or balloons, or mounted on a fixed object at high elevation. Data can be collected with a single overview shot that records the changing temperature of a specific area over time, or the data can be collected in transects to cover large areas while maintaining high spatial resolution. However, the surveyor must keep in mind that temperatures will change over time, so surveys should be kept short to maintain consistency. Ground control points must be placed around the survey area to allow georectification. Simple tin baking dishes staked to the ground will show up brightly as very cold areas at night, or highly reflective warm areas during the day. Plastic or wood ground control points are unlikely to be visible in the thermograms and are not recommended.

Archaeological features are not guaranteed to always produce visible thermal signatures even when they have distinct thermal properties. Radiation reflected from the surface or ground cover may obscure subsurface anthropogenic anomalies. Most thermographers choose to collect data at night to avoid this complication. Another obstacle can arise when a long stretch of stable weather allows temperatures of subsurface materials to equalize. Thermal surveys must be conducted while the temperatures of materials are still adjusting and differences are at their maximum.

Thermal surveys are most often successful when conducted after a shift in heat flux direction. The heat flux value $\emptyset$ denotes both the rate and direction of travel of heat from one material to another and is defined by Fourier's law: $\emptyset = -k\nabla T$. Essentially, a material with positive

heat flux is absorbing heat, while negative heat flux indicates that the material is losing heat. The larger the heat flux value (in either the positive or negative direction), the faster the change is occurring.

Deeply buried anthropogenic anomalies will be most visible after a shift in slow, transient heat flux. If a week of stable warm weather which has allowed all materials to reach thermal equilibrium is followed by a cold snap, materials with low thermal inertia will cool quickly, while those with high thermal inertia will remain warm. Thermograms collected during this transition period will reveal the strongest thermal anomalies (Périsset and Tabbagh 1981, 170–171).

Diurnal heat flux can also be revealing. Near-surface features or surface inclusions that reflect buried features will experience daily temperature variations, and so can stand out as anomalies after daily heat flux shifts. In contrast, seasonal heat flux changes are less productive. While seasonal temperature changes have deep penetration, other surface changes throughout the year caused by vegetation growth, humidity, and human activity create so much noise that most anomalies are obscured (Scollar et al. 1990, 597–598).

Data processing

After thermal video data are collected, surveyors extract still-frame thermograms to analyze individually or mosaic into a single image. Thermograms are stored as raster files wherein each pixel or cell represents an area and the average temperature in that area. These data can be imported to any geographic information system (GIS) program for further processing. It can be georeferenced to real-world coordinates and then compared with photographs, maps, or other geophysical data to aid in interpretation. The thermograms may also be filtered, resampled, and otherwise manipulated to highlight subtle thermal anomalies.

Bellerby, Noel, and Branigan (1990) tested three methods for filtering out surface noise created by diurnal variation, irregular topography, and soil inhomogeneities. They collected multiple temperature readings at each point in their survey

grid and at a base station. They used the first and last base station reading to interpolate a linear function representing the overall change in temperature over time. They then subtracted it from the total set of base station data. Finally, they converted the data into a Fourier series which represents the waveform pattern of temperature change over time and subtracted from the site grid data. Using this method to reduce thermal noise allowed them to isolate deep features from surface anomalies.

Occasionally an anthropogenic feature may not create a sufficiently distinct thermal anomaly to be visually identified in a single thermogram. In this case, it may be possible to locate the feature by identifying an associated temporal anomaly. This can be done by comparing multiple sequential thermograms of a single area. If a particular cluster of cells has significantly more or less temperature variance than its neighbors, this would indicate the presence of a material with higher or lower thermal inertia—that is, more resistant or more susceptible to temperature changes (Danese et al. 2010). This analysis can be done by calculating the standard deviation of corresponding cells across several thermograms using raster math. In the resulting raster, each cell would represent the temperature variance in that area.

Future directions

Aerial thermography is becoming increasingly popular as thermal cameras and drones become more accessible. Recent projects have demonstrated that aerial thermography is a highly productive survey methodology in arid areas such as the American Southwest and the Near East (see Further Reading). Ongoing research will inevitably lead to refinement in our understanding of survey timing based on seasonal and weather patterns as well as developments in data processing methodology. As the

technology and our ability to interpret the data improve, the suitability of aerial thermography will be expanded to include other regions.

Total Station

JOHN W. RICK

Stanford University, USA

Total stations are electronic surveying instruments that incorporate electronic distance measurement (EDM) to allow measurement of three-dimensional locations with a high degree of accuracy and precision (Figure 1). They are closely related to theodolites, electronic or otherwise, that do not have in-built abilities to precisely measure target distance from the instrument. Total stations measure horizontal and vertical angles to impressively low errors of about 0.00028–0.00139 degrees, sufficient to allow locating exact points up to a few kilometers away from the instrument. The EDM component of total stations emits infrared laser pulses that are reflected back to the instrument from the target of measurement. The amount of time elapsed (time-of-flight) in this rebound is used to precisely determine the distance between the instrument and the target. The resulting spherical coordinates (horizontal and vertical angles, and the measured radial distance out from the total station) that unambiguously determine the position of the target can be trigonometrically transformed into cartesian coordinates, typically measures of easting, northing, and height in relation to either the total station or an absolute datum. The electronics of the total station usually do all calculations, to deliver to the user the target's location in such XYZ site or global coordinates (Rick 1996).

Physically, a total station consists of a telescope capable of sighting the target, a keyboard to input the specifications of the user (coordinates, program commands, target codes, etc.), a display to deliver visual/numeric information to the user, the EDM (now usually incorporated within the rotating head containing the telescope), and a leveling base that usually sits on top of a strong tripod. In use, the total station is placed

above a known point or datum—or related to a series of known points—to fix the instrument's current position within a coordinate grid, and the directional orientation in that plane (e.g., the direction of north) and the instrument's height above that plane are determined. Once this setup is verified, the total station can sight, measure, and record target points within coordinate space at high levels of accuracy and precision. In practice, artifact locations, dimensions of architecture, site topography, and any other spatial features of a site can be recorded, usually to internal memory or a variety of memory devices of varied capacity. Two principal types of targets are used. Older instruments depend on targeting a mirror-like retroprism reflector mounted on a vertical, usually manually held and leveled rod which returns the laser pulses. More recent instruments add the possibility of reflectorless function, in which the laser pulses are reflected off the actual object of archaeological or topographic interest. In general, reflectorless function has a more limited measuring distance (originally under 100 m, but now closing in on the practical single reflector limitation of around 1 km), but offers the possibility of measuring locations in which a reflector cannot be easily placed, and also faster single-user operation.

Most total stations incorporate a number of programs that are useful in archaeology. Important among these is the “setting out” or “stake out” routine in which the coordinates of a point are entered, allowing the instrument to aid the user in finding the point, by indicating either the radial line and distance from the total station where the point should lie, or the necessary displacement north–south or east–west from a given position. This is particularly advantageous for laying out excavation units on highly irregular or sloping surfaces, where determining leveled horizontal distances is difficult with lesser instruments or by hand. Another useful program is free-station, or resection, in which the instrument's setup location is determined by measuring a series of known points, and calculating a least-squares

Figure 1 Total station in use at Chavin de Huantar, Peru.

Source: Photo by author.

solution, complete with error terms for distances and angles to each point. This allows great freedom in setup locations, and assures that any new instrument location is corroborated by a series of reliable points.

Obtaining or renting total stations may represent a significant expenditure for modest projects, and these sensitive instruments must be maintained conscientiously to be reliable. Cost can range from under US \$5,000 to well over \$30,000, depending on accuracy and features. Accuracy of course decreases at greater measurement distance from the instrument due to the diverging radial lines of potential readings. Most instruments range from 1 to 5 seconds of angular accuracy, meaning that at a typical long measurement distance of 100 m, expectable intrinsic errors of around 1–3 mm can be expected. No common spatial point location method currently competes with this accuracy, in the range of 0.001–0.003 percent error over a given distance. Advanced total stations have robotic features for tracking a reflector automatically, allowing a single operator with radio control to command point registration

while moving a reflective target to the points of interest (Kvamme, Ernenwein, and Markussen 2006). There is also a certain degree of unattended operation, in which advanced total stations can take reflectorless measurements within a defined field of view on an automatic basis.

The use of total stations articulates closely with other spatial technologies in archaeology (see FIELD SURVEY). Global positioning system (GPS) instruments that determine target locations based on signals from satellites can provide worldwide coordinates, useful to position more local total station measurements (see GPS (GLOBAL POSITIONING SYSTEM)). Some total stations include GPS measure capabilities. Laser scanners and photogrammetry quickly gather masses of three-dimensional data at the inter-site level, but require accurate base measurements to fix their collected data within the site's context (see LASER SCANNING and PHOTOGRAMMETRY AND STEREOPHOTOGRAMMETRY). Total stations are the most common option for this, because their millimeter accuracy is difficult to achieve by other methods, and because they do not require the satellite lines-of-sight of GPS instruments. At the same time, total stations require line-of-sight from the instrument to either the reflector or object target, sometimes an inconvenience in topographically or architecturally complex situations. Total stations have traditionally been somewhat difficult to comprehend and use, but increasingly well-programmed software, together with relatively large display screens allows a more user-friendly interaction between operator and device. Overall, most substantial excavation or mapping projects will benefit greatly from the competent use of total stations.

Underwater Three-Dimensional Laser Imaging

LUIGI DE DOMINICIS

ENEA—Italian Agency for New Technologies, Energy
and Sustainable Economic Development, Italy

Three-dimensional (3D) laser imaging systems are devices that emit a laser beam which shines on an object located at meters of distance and that record a portion of the laser light reflected back by the object's surface. The device processes the received signal and generates a 3D digital model of the object for visualization on a display, where each point of the object's surface is assigned a set of spatial coordinates in a relative reference frame.

The application of 3D laser imaging systems in archaeology and heritage on emerged land has been steadily growing since the 2000s, mainly in view of the considerable progress in optoelectronic technology. Successful applications have been demonstrated for operations at tens of meters of distance from the targeted object (range) and with submillimeter spatial resolution (accuracy).

Transposition of 3D laser imaging technology to the underwater environment is not straightforward, however, and recording 3D models of subsea archaeological sites is of key importance to make available to experts a valuable set of data for drawing documents, cataloguing, and planning preservation and restoration interventions.

The presence of a column of water between the laser-based device and the target and the demand to operate at depth introduce severe scientific and technological challenges. Many of them have been successfully addressed in recent years and this is why underwater 3D laser imaging technique is slowly but steadily bridging the gap with respect to its homologous counterpart on emerged land.

To begin with, water is a dissipative transmission channel for laser light, with detrimental

effects on the range and accuracy of underwater 3D laser imaging systems. In fact, water attenuates laser light as it propagates through the aqueous medium and with an exponential law. If I_0 is the laser beam intensity as emitted by the underwater 3D laser imaging system, the intensity I_z at a distance z in the aqueous medium is given by:

$$I_z = I_0 e^{-kz}$$

where k is the attenuation coefficient that is the sum of two terms: k_a , the absorption coefficient, and k_s , the scattering coefficient. Both coefficients have the dimension of the inverse of a length and show a pronounced dependence on the laser beam wavelength λ . Absorption is the process by which water removes a fraction of the optical energy from the laser beam, ultimately converting it into heat. With the scattering process, water redistributes part of the optical energy of the laser beam into spatial directions other than that of the laser beam propagation.

In the clearest oceanic waters, k_a dominates with respect to k_s and the minimum value for k is nearly 0.02 m^{-1} at $\lambda \sim 410 \text{ nm}$. As water turbidity increases, k_s becomes the prevalent contribution and the values of k range from 0.1 m^{-1} for least transparent oceanic waters to 1.2 m^{-1} for coastal areas at $\lambda \sim 530 \text{ nm}$.

This means that in the most transparent oceanic waters, 3D laser imaging systems based on laser-emitting radiation in the 405- to 450-nm region are best suited, with potentiality of operation up to 10 m range.

On the other hand, in the least transparent oceanic waters and in coastal zones, only short-range operations are possible (up to 3 m), using systems based on lasers emitting light in the green region of the electromagnetic spectrum.

The necessity to operate at depth introduces other factors of merit for an underwater 3D laser imaging system beyond range and accuracy. Such factors are related to the technological challenge of marinizing the system and making it qualified to operate in real underwater scenarios. Among them, *size* and *weight* are the most important.

In fact, an underwater 3D laser imaging system could be operated in two ways: deployed on tripods on the seabed, offering a stable platform; or installed onboard a remotely operated vehicle (ROV). The first case is pursuable only in the relatively shallow waters accessible to divers who incrementally reposition the tripod in order to cover the entire structure to be visualized with the field of view of the sensor. When mounted on an ROV the sensor must be stably fixed to it and accommodated together with other sensors like cameras, sonars, robotic arms, and samplers. In this case, the 3D laser imaging system is hardwired through the ROV tether to the operator controlling the vehicle from a ship above the inspected site. Mainly for ROV operations, another key performance indicator is the *maximum depth of operation*. The housing of the device must be qualified to operate at the depth of interest for the specific applications, which in some cases are conducted in deep waters. Common to the diver-assisted and ROV operation is the issue of the *vibration and shock resistance* of the sensor, which determines its capacity to withstand the hard operative conditions found in underwater environments. For instance, during survey missions with ROVs, acceleration up to 4g is routinely achieved. Finally, the device must be *robust to thermal cycling* due to the thermal gradient suffered by the sensor during the initial deployment at sea level and further operations in proximity of the seabed.

Laser sensors for 3D imaging in underwater environments share a basic scheme with their homologs used on emerged land: a launching stage emitting the laser light that illuminates the target and a receiving stage detecting the signal to be processed for generating the 3D model. The laser can be a spatially collimated beam hitting the target surface at a single point, a laser stripe projecting a line onto it, or an expanded fan illuminating the whole target surface in one shot. The range information is encoded in a measurable parameter of the fraction of the laser light reflected back by the target and recorded by the receiving stage.

In *triangulation systems* the range information is encoded in the spatial position on the receiving sensor of the optical signal recorded. In these systems, the launching stage and the receiving stage are separated by a distance x (baseline), and

if d is the range to measure, the error δd in range estimation (accuracy) scales as d^2/x . This explains why underwater 3D laser imaging systems based on the triangulation technique have a limited operative range of a few meters. The possibility to reduce δd by adopting a large baseline is pursuable, but at the expense of the device's size and field of view. Underwater triangulation systems are based on continuous lasers and adopt a laser stripe as the illuminating beam and a 2D imaging array as the receiver. This allows reducing the 3D model acquisition time by sweeping the laser stripe on the target surface. Recently, a commercial system based on triangulation and with a baseline $x = 50$ cm has been successfully used for recording the accurate 3D models of a shipwreck in Thunder Bay Marine Sanctuary, the United States (2G Robotics 2016) and with an operative range $d \sim 5$ m. The device was mounted on a tripod and laid on the lake bed for the 3D model acquisition.

Another class of underwater 3D laser imaging system is based on time-encoding methods. This means that the range information d is retrieved after having measured a temporal parameter of the laser beam. Among them, the most advanced devices are those operating with the *time-of-flight* method. These systems are based on a laser emitting pulses in the picosecond or nanosecond time regime and spatially collimated. The range information is encoded in the round-trip time of the laser pulse traveling from the launching stage to the receiving stage after having been reflected back by the target surface. If $t = 0$ is set as the instant at which the laser pulse is emitted at the launching stage and Δt is the measured round-trip time, the range d of the point on the target surface sampled by the laser beam is given by

$$d = (c\Delta t/2n)$$

where c is the velocity of light in the vacuum and n is the index of refraction of the aqueous medium.

In order to measure Δt with high precision and to achieve submillimeter values for δd it would be necessary to use pulses in the picoseconds time regime, whose generation requires bulky laser sources. Nevertheless, a better trade-off between range accuracy and the sensor's size and weight is achieved with laser pulses in the nanosecond

time regime. In fact, this allows using less bulky laser sources, while submillimeter range accuracy is ensured by the adoption of more sophisticated detection and data processing methods. One of the advantages of the time-of-flight system is the possibility to drastically cut the optical noise produced by the fraction of the laser beam that is backscattered by the aqueous medium and that falls into the receiver field of view with appropriate time-discriminating detecting methods. For typical oceanic waters with $k \sim 0.1 \text{ m}^{-1}$, underwater 3D laser imaging systems based on the time-of-flight method can reach a range accuracy of 30 mm at 10 m of range. Successful applications of these kinds of devices have been demonstrated both for operation onboard ROVs during several survey missions for the offshore oil and gas industry and in static operation once deployed on a tripod in the turbid water of a lake for 3D model acquisition of shipwrecks (3D at Depth 2016).

Always based on a time-encoding method are the underwater 3D laser imaging systems using intensity-modulated laser beams and working with the *MODEM* (MODulation/DEModulation) *technique*. These devices are essentially phase-shift sensors that measure the phase delay $\Delta\phi$ that the intensity of a laser beam modulated at a frequency f_m acquires during the path from the launching to the receiving stage. If d is the range of the point on the target surface sampled by the laser beam, the following relation holds:

$$\Delta\phi = 4\pi n d f_m / c$$

The pioneering work of Mullen et al. (1995) demonstrated that the intensity-modulated component of the laser intensity backscattered by the aqueous medium has a low-pass filter dependence on f_m . This means that for operation at modulation frequencies f_m greater than a cut-off value f_{co} , the receiving stage is less sensitive to the backscattered laser radiation. The cut-off frequency f_{co} is inversely proportional to the attenuation coefficient k and for typical oceanic waters has a value around 100 MHz that is easily obtainable with current laser technology. Range accuracies of the order of 5 mm have been attained with a prototype sensor based on an

intensity-modulated laser and in turbid water with $k = 0.3 \text{ m}^{-1}$ and at a range of nearly 3 m (De Dominicis et al. 2010).

The visual rendering of 3D models recorded with underwater 3D laser imaging systems is provided in a scale of grays according to the level of reflectivity of the target surface to the wavelength λ of the laser beam mounted on the sensor. The potential to generate colored 3D models of submerged targets has been demonstrated in a laboratory experiment using an intensity-modulated system where the output of three different lasers with wavelengths in the red, green, and blue regions was mixed to generate a single laser beam that measured the target surface reflectance at the three wavelengths.

Archaeological Sciences

MARCOS MARTINÓN-TORRES

University of Cambridge, UK

Archaeological sciences and *archaeological science* are generic terms commonly used to refer to the many subdisciplines that involve the application of science, technology, engineering and mathematical methods in archaeology. Most frequently defined by their methods rather than by specific aims or study areas, archaeological sciences cover the engagement of a wide range of disciplines such as physics, chemistry, biology, genetics, computing, or medicine to the study of both organic and inorganic archaeological remains, as well as associated sediments or contextual information such as their date or spatial location.

Most archaeological sciences generate primary data about aspects of the composition and microstructure of archaeological samples and reference materials, which in turn allow inferences about subsistence (e.g. through bone isotopes that inform about diet (see DIET AND CARBON ISOTOPES and DIET AND NITROGEN ISOTOPES)), or organic residue analyses in cooking pots (see ORGANIC RESIDUE ANALYSIS), health (e.g., identifying paleopathology (see PALEOPATHOLOGY)), environment (e.g., through pollen identification (see PALYNOLOGY) or zooarchaeological analysis (see ZOOARCHAEOLOGY)), technology (e.g., through metallographic analyses (see METALLOGRAPHY) or ceramic petrography (see PETROGRAPHY AND CERAMICS)), trade (e.g., through geochemical provenance studies (see CHERT, SILEX, AND OBSIDIAN SOURCING)), migration (e.g. through ancient DNA (see DNA: NEXT GENERATION SEQUENCING and DNA: MITOCHONDRIAL)), and other aspects of past lifeways. In addition, archaeological sciences are useful in the identification and survey of archaeological sites (e.g., in remote sensing (see AIRBORNE REMOTE SENSING)), conservation, documentation, and heritage management. Computing and mathematics are sciences often used for the processing

and analysis of primary data (see STATISTICS IN ARCHAEOLOGY), as well as to develop predictive models (see PREDICTIVE MODELING).

It is important to differentiate between *archaeological science* on the one hand, and *scientific archaeology* on the other. Advocates of scientific archaeology predicate the conviction that archaeology should model its methods of inquiry and inference upon those of the natural sciences, irrespective of whether the strategies employed to generate the data are borrowed from advanced science and technology or not. For example, scientific archaeologists often try to falsify hypotheses using archaeological evidence, and apply theories from evolutionary biology to generalize about past cultural behavior. Conversely, archaeological science refers to the development and application in archaeology of techniques and concepts drawn from the natural sciences and engineering, without exclusive reference to any theoretical persuasion. As such, an archaeological project may be framed in postpositivist and relativist theory, and hence negate the possibility of offering any objective facts or generalizations about the past, but still incorporate data obtained with scientific instruments.

Archaeometry (see ARCHAEOOMETRY) is often used as a synonym of archaeological science, although the former term tends to be restricted to the study of sites and inorganic materials rather than biogenic materials. Another relevant term is *heritage science*, which is defined as encompassing “all technological and scientific work that can benefit the heritage sector, whether through improved management decisions, enhanced understanding of significance and cultural value, or increased public engagement” (Williams et al. 2013, 7). Even though some claim that archaeological science is a subdiscipline within heritage science, in practice both fields can share methods but tend to be very different in their aims, scope, and study objects: While archaeological sciences are mostly concerned with making inferences and answering questions about past societies, heritage science tends to be more concerned with the preservation, management, and public

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0030

use of individual heritage items in the present. There are, however, many synergies and overlaps among all of these fields, and sometimes the term employed by a particular researcher or team may respond more to academic traditions or branding than to real distinctions.

Natural scientists applied scientific reasoning to infer the relative ages of some archaeological sites from the late-seventeenth century, some 200 years before the emergence of archaeology as a discipline. By the early twentieth century, pioneer geoarchaeologists, dendrochronologists, zooarchaeologists, and archaeological palynologists sought close cooperation with archaeologists, often doing joint fieldwork with them. Numerous scientists also contributed occasional studies of archaeological materials such as ceramics or metals, though many of these were published as unintegrated appendices. By the 1960s, laboratory-based chemical, provenance, and dating studies were widespread in Europe and America, partly thanks to a renewed optimism about the potential of science in archaeology, and to concerted efforts to ring-fence and fund archaeological science projects (Killick and Young 1997). However, inflated expectations and problems of cross-disciplinary communication led to some frustration and failed efforts, with scientific data often devoid of archaeological interpretation or significance, and not incorporated in core archaeological narratives. The problem was often blamed on the reluctance of scientists to engage with archaeological concerns, although many archaeologists were also guilty of failing to learn about the potentials and problems of science and technology so that they could make more informed requests (Olin 1982). These disagreements led to a backlash against what was perceived by some as an intromission of scientists in archaeology. The retreat was fueled by a growing influence of postmodern relativistic theories in the archaeology of the 1980s and 1990s, which seemed incompatible with the claimed objectivity of science (De Atley and Bishop 1991; Jones 2002). Since 2000, archaeology and science have been increasingly integrated, and the majority of the most significant research topics and findings in archaeology have input from the sciences in both their conception and implementation. This is in large part due to the growing institutionalization of training in

archaeological science, with university degrees that are explicitly concerned with both archaeology and science, and which typically involve staff from different backgrounds and/or departments. As a result of this process, there is a generation of graduates with interdisciplinary training that are ideally suited to facilitate synergies (Martínón-Torres and Killick 2015; Pollard and Bray 2007).

While some archaeologists still see the sciences as a subservient partner whose only role is to produce data, interdisciplinary archaeological scientists have made countless contributions to archaeological research agendas, theories, and models, often driving major developments in the discipline. For example, a surge of research on ancient models of trade and exchange in the 1980s was encouraged by the availability of geochemical provenance studies, which allowed linking artifacts to their source. Discussion of diffusionism versus independent development of multiple phenomena was initially stimulated by developments in dating techniques and, more recently, by high-resolution characterization of technological traditions that can inform about modes of knowledge transmission. Comparative approaches to plant and animal domestication, their pace and cultural significance are led by better sampling strategies, improved microscopy and, increasingly, DNA and statistical reanalysis of legacy radiocarbon dates. It is generally accepted that human evolution can only be understood by drawing on theories and data from science-based anthropology and biology. Core archaeological subjects of clear relevance in the contemporary world, such as agency and identity, are best informed by the combination of genetic, geographic, and cultural data enabled by the archaeological sciences (Martínón-Torres and Killick 2015).

This picture is applicable, to different extents, to the academic and institutional environment in the United Kingdom and United States, in addition to some universities and research centers in Belgium, France, Germany, Italy, Scandinavia, Spain, Israel, South Africa, China and Japan (Killick 2008). In these contexts, attempting to demarcate archaeological science as a branch separate from mainstream archaeology is becoming increasingly irrelevant, since very few would deny that archaeology, like any other academic

discipline, only realizes its full potential when empowered by science. However, the growth of archaeological science is geographically uneven, with many developing countries lagging behind because of difficulties in access to instrumental facilities and relevant training. As such, the development of balanced international partnerships has been identified as one of the major challenges for archaeological sciences in the medium term (Killick 2015). Another major hindrance for the development of archaeological science in some countries has been the reluctance by some governments to allow invasive sampling of heritage objects and/or the export of samples to countries with suitable laboratories. Even though portable and noninvasive analytical techniques have made major strides to overcome these problems, some fundamental techniques still require samples. Most archaeologists favor negotiated decisions that consider the uniqueness of the objects and their heritage value but also the enhanced information and public interest obtained through scientific analyses.

The interdisciplinary collaboration between natural sciences and archaeology has also led to an increased acceptance of the protocols of science as benchmarks for the quality of archaeological research, particularly as regards rigorous data acquisition, reproducibility, and curation that may facilitate validation and reanalysis. The impact of archaeological theories and inferences in the sciences has been more limited, however, and this is another area with great potential for future developments: While archaeology has contributed to reformulations in ecology, including key input to current discussion of the Anthropocene and the management of climate change, scientists are yet to take significant notice of archaeological lessons in other crucial arenas. These arenas include, among others, a time-deep understanding of the contexts that trigger creativity and innovation, the development of productive and socially responsible forms of public engagement, and the use of flexible research frameworks that take advantage of science but accept more methods than the deductive-nomological prescription.

Archaeology

SANDRO SALVATORI

Centro Studi Sudanesi e Sub-Sahariani, Italy

“Archaeology is an undisciplined empirical discipline. A discipline lacking a scheme of systematic and ordered study based upon declared and clearly defined models and rules of procedures” (David L. Clarke 1968: xiii).

Archaeology as an academic discipline is firstly a body of excavation techniques used in the recovery of artifacts and biofacts, human and animal bones; overlaying this is the body of theoretical constructs developed to study and understand, in a social and historical perspective, the organization of human societies through the material evidence brought to light by the archaeologists' tools.

Actually, after an initial stage marked by an antiquarian approach firstly appearing in the Roman world (e.g., the astonishing collection of Greek Hellenistic statues assembled by the Roman Emperor Tiberius at Sperlonga cave), a more structured interest in Greek and Roman art works and culture emerged in the Renaissance period. Following this, a new approach to ancient materials was developed from the mid-eighteenth and early nineteenth century by the scientific method which denotes the Age of Enlightenment, with the publication of the *“Encyclopédie, ou Dictionnaire Raisonné des Sciences, des Arts et des Métiers,”* and Positivism, from Claude Henri de Saint-Simon (1760–1825) to Auguste Comte (1798–1857). This was characterized by systematic data collection and ordering. The discipline at the same time went through a period of diversification into different branches including Prehistoric archaeology, Classical or Historical archaeology, Egyptology, Assyriology, North, Central and South American archaeology.

By the mid-nineteenth century, archaeology had moved towards a cultural–historical approach to explain human origins and cultural change, following the advent of Darwinian evolutionary theory and to reflect new achievements in biological and geological sciences. A new wave of archaeological excavations started and continued during the first half of the twentieth century in the Near and Middle East, as well in Europe, Egypt, and the Americas, with the first interdisciplinary projects like the Carnegie Institution Anau excavations in the Turkmenistan piedmont (Pumpelly 1908).

In the 1950s the discipline experienced what is known as the radiocarbon revolution which provided archaeology with an absolute dating (see DATING IN ARCHAEOLOGY) instrument to construct cultural chronologies. This was later followed by other methods such as uranium–thorium (see URANIUM-SERIES), optically stimulated luminescence (see OPTICALLY STIMULATED LUMINESCENCE), archaeomagnetism (see ARCHAEOMAGNETISM), amino acid racemization, bone-nitrogen, potassium–argon, obsidian hydration (see OBSIDIAN HYDRATION DATING) among others. A few years later a broader and more inclusive approach to archaeology as an anthropological discipline was inaugurated by the well-known North American and British movement of the New or Processual Archaeology. At the beginning, the movement was characterized by a search for general laws moving from description towards an explanation of human cultures and cultural change all along the sequence from the Palaeolithic up to the present. The movement also focused on new branches of the discipline, such as ethnoarchaeology (see ETHNOARCHAEOLOGY). The New Archaeology movement is usually considered as a turning point (or a revolution) in archaeological practice and an elaboration of theoretical constructs pointing to the explanation of cultural change and its interconnection with climatic and environmental changes (Trigger 2006).

An important contribution to the new directions undertaken by the archaeological discipline

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0033

was offered by the advancement of the scientific techniques and methodologies in the material sciences as applied to archaeological materials (see SUBSTANCES AND MATERIALS and ARCHAEOLOGICAL SCIENCES). Beginning with particular studies which usually appeared as appendices in archaeological excavation reports, the contribution of the physical sciences to archaeology started to provide more focused and expanded instruments to nuance explanations of cultural evolution, to environmental and climatic fluctuations, and to material production technologies (e.g., Heizer and Cook 1960; Pyddoke 1963).

Critiques of the New or Processual Archaeology have been advanced on occasion by proponents of a Postprocessual or Contextual archaeology and the more extremist aspects of the movement have now been at least partly abandoned, even by its leading proponents. The new movement was characterized by a rejection of positivism (see POSITIVISM) in favor of relativism owing a debt to the French Marxism and structural anthropology. However its most important achievements have been recently reconsidered and accepted by processual archaeologists.

The original search for general or covering-laws, later translated into an attempt to produce a paradigmatic theory in archaeology (see PHILOSOPHY OF SCIENCE), has largely been abandoned or, at least, deeply questioned due to the basic ontological and epistemological fallacies of both the Processual and Postprocessual thinking (see Wallace 2011). A more pluralistic approach has evolved in the last 20 years, producing strands of theories which attempt to explain human evolution, cultural adaptation and change, diversity and multiplicity, as well as identifying processes shaping the materiality of societies. Among the new trends that, apart from the usual emphasis placed upon them by their proponents, can be considered as part of a unique interpretive toolkit, we can mention agency theory (see MATERIAL AGENCY), social brain hypothesis, evolutionary theory (see EVOLUTIONARY THEORIES), human niche-construction theory, entanglement theory (see MATERIAL ENTANGLEMENT), resilience theory, cultural transmission theory, behavioral theory (see BEHAVIORAL ARCHAEOLOGY), symmetrical archaeology (see SYMMETRICAL ARCHAEOLOGY), and finally a growing interest in

the materiality of identity processes as a powerful tool for the understanding of social organization, social cohesion, ideological constructs, allegiances, and conflictuality when contextually observed.

In spite of general advances in archaeological thought (Trigger 2006) some criticalities can be pointed out. Archaeological practice can be synthetically described according to four consecutive steps, useful to highlight major shortcomings in the discipline:

1. *Archaeological project design*: All research and rescue archaeological projects need a precise plan regarding the cultural objectives, planning of the team composition required in the field, together with the proper archaeological staff, of bioarchaeologists, geomorphologists, conservators, surveyors, and possibly of other scientists that will be involved in the analytical processes of the postexcavation procedures.
2. *Survey and excavation*: a good technical standard in regional or site survey (see FIELD SURVEY), excavation procedures (see TERRESTRIAL EXCAVATION), materials and systematic samples collection (see ARCHAEOLOGICAL RECORD), and field recording techniques (see ARCHAEOLOGICAL FIELDWORK) has been attained, although in some cases, fortunately a minority, survey and stratigraphic excavation techniques and sample systematic are not properly followed. What is still lacking are strict protocols, both in surveying procedures and material collection, however, the contribution from biology, geochemistry, genetic, mineralogy, and other sciences is pushing archaeologists to establish such protocols to allow inter-site and regional comparisons to deal with the high variability and multiplicity of the social and economic organization of human groups. As an outstanding example of inclusive project organization we can mention the renewed excavation at the Neolithic site of Çatalhöyük.
3. *Postexcavation*: over the last 20 years this phase of archaeological research has seen a more comprehensive approach where archaeologists and scientists of different scientific branches have collaborated both

in the field and laboratories to gain a more effective understanding of human societies' cultural processes. However, this growing phenomenon needs a cultural revolution that necessitates more effective communication among archaeology and other scientific disciplines to overcome the distance between the humanities and hard science languages. It in practice requires the archaeologist to be trained, through university courses, to deal with the basic "language" of hard sciences and, on the other side, for scientists to be trained to properly understand the basic principles and directions of the archaeological discipline. Recent publications, however, are helping to highlight opportunities and cultural limits in the integration process of hard sciences in archaeology.

4. *Publication*: finally we have to bemoan the persisting dominance of traditional approaches to the final publication of archaeological excavations with scientific reports confined separately in adjoined sections of the reports. Nevertheless, the marriage between hard sciences and archaeology, celebrated over the last 20 years, will surely generate new archaeological questions and new avenues for more inclusive and broad-based narratives on the history of humankind.

FURTHER READINGS

Archaeometry

MICHAEL TITE

University of Oxford, UK

The emergence of the term archaeometry was a direct consequence of establishing the Research Laboratory of Archaeology and the History of Art at the University of Oxford in 1955. The Oxford Research Laboratory was founded through the combined efforts of a physics professor, Lord Cherwell, and an archaeology professor, Christopher Hawkes, for the application of the physical sciences to the solution of archaeological questions (Hawkes 1986). In the beginning, the Research Laboratory was principally concerned with the chemical analysis of pottery, and metal artifacts and coins; physical methods of dating such as magnetic dating (see *ARCHAEOMAGNETIC DATING OF BAKED CLAY FEATURES*) and, later, thermoluminescence dating (see *DATING CERAMICS AND LUMINESCENCE*); and prospecting for buried archaeological features such as kilns, pits, ditches, and roads using proton magnetometers (see *MAGNETOMETRY*).

The term archaeometry was then devised by Professor Hawkes in 1958 as the title of the Research Laboratory's Bulletin in which its early research was first published. The Bulletin very soon started to publish contributions by authors from other institutions, and thus became the international research journal, *Archaeometry*, of which there are now more than 50 published volumes.

The Oxford Research Laboratory also provided the impetus for the beginning of regular international archaeometry symposia. In 1962, a training course was organized for archaeologists who had purchased proton gradiometers (see *GRADIOMETRY*) from the Laboratory. During subsequent years, regular reunions of these gradiometer users were held in Oxford. Gradually the scope of these reunions expanded to cover other aspects of archaeometry until they eventually evolved into the annual (now biennial) International

Symposium on Archaeometry, of which there have now been more than 40.

In part because of the physical science base for the emergence of the term, archaeometry has tended to have been used in the context of artifact studies, physical methods of dating, and prospection for buried archaeological features, although both the journal and the symposia now routinely include biomolecular studies such as the analysis of organic residues in pottery (see *ORGANIC RESIDUE ANALYSIS*), stable isotope analysis of bone (see *DIET AND CARBON ISOTOPES* and *DIET AND NITROGEN ISOTOPES*), and DNA analyses (see *DNA: NEXT GENERATION SEQUENCING* and *DNA: MITOCHONDRIAL*). However, in new developments from the mid-1970s onwards, the term archaeometry has tended not to be used. Instead, terms such as science-based archaeology, scientific methods in archaeology, archaeological sciences, and archaeological science have been used to describe funding bodies, new undergraduate and postgraduate degree courses, and new lectureships and professorships.

As a result, with the exception of its use for the journal and symposium, archaeometry is now a more-or-less obsolete term, and has been subsumed and replaced by the term archaeological sciences (see *ARCHAEOLOGICAL SCIENCES*), which embraces the application to archaeology of the environmental and biological sciences, as well as the physical sciences.

Archaeomineralogy

GEORGE RAPP

University of Minnesota Duluth, USA

The term archaeomineralogy is comparatively new. It was used by Rapp for a book, and by Rapp (2008) and by Kostov as part of the first international meeting on archaeomineralogy held in Sofia, Bulgaria. Archaeomineralogy is quite distinct from the history of mineralogy. It can be considered a subdiscipline of geoarchaeology (see GEOARCHAEOLOGY) as it covers the exploitation of rocks and minerals since ancient times for medicines, implements, ornaments, building materials, paints, and as raw material for metals, ceramics, and other processed products. Archaeomineralogy seeks to date, source, and characterize artifacts made from earth materials. Mineralogy as a field of investigation is closely connected to geosciences such as geology, petrology, and geochemistry, although it also has the strong tendency to embody the methods and techniques of modern crystallography and advanced materials science.

Archaeomineralogists, although not called by this term, go back to ancient times and were located around the globe. Among the most prominent were the Hellenistic Greek philosopher Theophrastus (ca. 372–287 BCE), the Greek physician Dioscorides (ca. 40–90 CE), the Italian Pliny the Elder (ca. 23–79 CE), the Spaniard Isidore of Seville (ca. 560–636 CE), the Arab authors Al-Biruni (973–1048) and Avicenna (980–1037), the Chinese Su Song (1070), the Italian Albertus Magnus (ca. 1206–80), and the German Georgius Agricola (1494–1555). Sanskrit texts from India mention the use of a wide variety of minerals in medicine (Rapp 2009). Modern practitioners of archaeomineralogy are mostly either geoarchaeologists who specialize in geology or lithology and have a background in mineralogy or petrology (origin and composition of rocks) or historians of science. Arguably, their mineralogical background makes them ideally

suited and well equipped to meet the demanding challenges posed by archaeometric analysis and conservation problems (Artioli 2010; Artioli and Angelini 2011).

Recently, provenance determination has become a significant aspect of archaeomineralogy. The provenance of exploited rocks and minerals can lead to the determination of trade routes, economic history, and other important aspects of society.

Ancient Egyptians had one of the best understandings of mineralogy and lithology in the practice of medicine and the manufacture of monuments and ornaments (Lucas and Harris 1999). Rock names such as basalt, syenite, porphyry, and alabaster have their origins in Egypt. The igneous rock “basalt” appears to have the oldest roots, in use as early as 2000 BCE. The Egyptian doctors knew the antacid properties of limestone and used kaolin to extract water or toxins from the stomach. They used approximately 20 minerals in medicinal preparations, including ruby, sapphire, emerald, jade, topaz, garnet, and feldspar, as well as pearl, coral, and shell. Ancient Mesopotamians also had a well-developed understanding of rocks and minerals for medicinal and industrial uses. Cuneiform texts record the use of minerals for medical treatments and a variety of drugs.

In ancient times, color was by far the most important character to classify rocks and minerals. Colors had significant symbolic attributes such as purity, passion, danger, and mourning. Many minerals and rocks had medicinal and magic properties. Alchemists equated color with the true nature of a substance. Modern understanding of the physical and chemical nature of mineral properties was established only in the early nineteenth century by Joseph-Louis Proust's law of constant composition in 1799, John Dalton's atomic theory in 1805, and the development of accurate methods of chemical analysis.

Early rock and mineral identification was chancy, most often relying on color alone. Names given to many mineral species have changed over time and even today some minerals have a variety of names and synonyms. For example, over 40

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

© 2018 John Wiley & Sons, Inc. Published 2018 by John Wiley & Sons, Inc.

DOI: 10.1002/9781119188230.saseas0039

names have been given to opal and its varieties. More than a thousand names have been given to rock lithologies. Nevertheless, sorting out what rocks were exploited in antiquity is somewhat easier than for minerals.

The feldspars are the most common minerals in the Earth's crust and are major constituents in most igneous rocks. In the Americas, ancient societies used semiprecious varieties (sunstone, moonstone, and amazonstone) as gems. Moonstone shows an opalescent play of colors. Amazonite was used as a gem by the pharaohs of Egypt and the kings of ancient Ur. In the New World, it was exploited by the Aztecs and the Maya.

The other mineral group that was widely available and extensively exploited was the quartz family (Götze and Möckel 2012). Rock crystal is colorless and transparent quartz. Vessels and spheres have been formed from large quartz crystals over vast time and space. Rock crystal and agate were favorite semiprecious stones throughout early China.

Quartz was used widely in gems, beads, seal stones, and ceremonial objects. The Greeks knew how to use shaped quartz crystal to concentrate the sun's rays to start fires. Many varieties of quartz have been used as semiprecious stones such as amethyst (purple or violet), citrine (yellow), and carnelian (red). Agate is varicolored microcrystalline quartz, often with irregular or concentric bands. The earliest use of agate was in Mesopotamia, where ornaments and tools have been recovered. Agate was the preferred stone for crafting signets, stamps, and seal stones throughout the ancient Near East. The area of Idar-Oberstein in Germany supplied agate to the Greeks and Romans.

Another silica mineral, opal, is a glassy not a crystalline material. The name opal may have been derived from the Sanskrit word *upala* meaning precious stone. For the Romans, opal ranked second only to emerald as a noble gem. Mexico's ancient societies had many sources of precious opal. Ordinary opal was used in the New World for projectile points. Another glassy material is obsidian, a normally black volcanic glass widely available in young volcanic terrain but entirely absent in other geologic settings. Although mainly used for tools and weapons, it was also made into ornaments. Neolithic sites in Anatolia are particularly rich in obsidian artifacts.

Obsidian also was important in many New World contexts. The Aztecs used obsidian for projectile points, knives, razors, swords, mirrors, and ornaments. Obsidian Cliff in Yellowstone National Park is one of the high-grade obsidian deposits in western North America.

Many silicate minerals have been used as gems (see GEMSTONES) because of their hardness and variety of colors. Sugilite, a relatively rare pink to purple silicate mineral, is one of a number of unusual gemstones found in Japan. Another is gem-quality hornblende.

Garnets are found on every continent except possibly Antarctica. The gem varieties are grossularite, almandine, pyrope, rosolite, hessonite, andradite, and uvarovite. Color is the most obvious feature of gem garnets. The garnet group shows one of the widest varieties of color in the mineral world, ranging from colorless, through white, gray, yellow, yellowish green, green, yellowish brown, brown, pink, red, and black. Only blue is missing. Principally used as a gemstone, the name grossularite originates from the Latin *grossularium* (gooseberry). During the Middle Ages, deep blood-red almandine garnet was preferred as a gemstone for decorating religious artifacts.

Lapis lazuli is known for its blue color, which can vary from deep blue, indigo blue, azure blue, and violet blue to greenish blue. Its name is derived from the Latin word for stone and a Persian word for blue. The only proven ancient source of lapis lazuli in the Old World is Badakhshan, Afghanistan (Moore and Woodside 2014). Lapis lazuli found its way to the Indo-Pakistani region by Neolithic times. The mines of Badakhshan were described by Marco Polo, who visited them in the thirteenth century. Importation of lapis began as early as the Third Dynasty at Ur for cylinder seals and beads. It found its way into Egypt by Predynastic times.

Jade is the gem term used for two different minerals, jadeite and nephrite. Jades have been worked into ornaments and implements since Neolithic times. Usually thought of as a gemstone, the toughness and ability to hold a sharp edge made jade a useful tool and weapon material. Ancient China is well known for its use of jade. As early as the Han Dynasty, Chinese craftsmen had the ability to distinguish true jade from look-alike imposters. Chinese jade (nephrite),

however, did not come from China. It came from nearby Burma and Turkistan.

Beryl may occur in gem forms as emerald (green), aquamarine (blue), or morganite (pink-red). Emeralds were Cleopatra's favorite gemstone. The earliest emeralds were mined from the legendary Cleopatra's Mines in the Sikait-Zabara region of Egypt. Until the Europeans discovered emeralds in the New World (Colombia and Brazil), Egypt was the only source. In India's most famous temple, dedicated to the goddess Minakshi, her idol is made of emerald, most likely carved out of a single crystal. Aquamarine is a beautiful sea-blue variety of beryl. The color is caused by iron ions in the crystals. The best of the gem-quality aquamarine is found in Brazil, where it occurs in pegmatites and associated alluvial deposits of gravel. Other localities include Russia's Ural Mountains, Afghanistan, Pakistan, and India.

Chrysoberyl has long been a favorite gemstone because of its beauty and hardness. It is found in two varieties, alexandrite and cat's eye. It has an extensive color range and can be found in various shades of yellowish green, yellow, gray, brown, blue green, and emerald green. Its name is taken from the Greek word *chrysos* (golden) and from the mineral beryl, in allusion to its color and beryllium content. The variety alexandrite is unique because the color depends on the light source. It is green or blue green in daylight and under fluorescent light, but shades of red when seen in incandescent light. Alexandrite was discovered in the 1830s in Russia's Ural Mountains and named after the future Czar of Russia, Alexander II.

Turquoise has a color that varies from bright blue, pale blue, sky-blue, bluish green, apple-green, to greenish gray. It is one of the oldest known talismanic and curative gems, prized by many societies worldwide. Turquoise was used in ancient Egypt prior to the First Dynasty, with mines operated in the Sinai Peninsula by the fourth millennium BCE. Turquoise was mentioned by the Arab mineralogist ibn-Mansur in 1300 CE. Turquoise has been exploited in China for more than 3,000 years, at least back to the late Shang at Anyang. There are a significant number of turquoise deposits in the southwestern United States, that continued to be worked and were exploited by ancient groups.

Corundum is found in two gem varieties: ruby and sapphire. Ruby is red in color and takes its name from the Latin *rubeus* (red). According to medieval Arab scholars, this stone was mined in Sri Lanka. Pliny listed sources as India, North Africa, Caria, Ethiopia, Miletus, Orchomenos, Chios, Corinth, Troezen (in Greece), Marseilles, and Lisbon. Sapphire is found in shades of blue and sometimes yellow. Sapphire is an ancient term of uncertain origin, possibly related to Hebraic *sappir* and Sanskrit *sanipruja*. Sapphire was used as a gemstone beginning in the early first millennium BCE.

Amber is not a mineral, but rather fossilized resin exuded by several plants, such as the conifer *Pinites succinifer* (Artioli and Angelini 2010). The name is taken from Arabic *acnbar*. Some varieties are called succinite (or Baltic amber) and retinite. Amber has a hardness of only 2.5–3.0. Artifact amber is quite susceptible to weathering and to poor conservation techniques. The color ranges from golden yellow through orange, red, brown, green, violet, and black. It can be transparent to opaque. Amber from various sources, when exposed to ultraviolet light, will fluoresce with different colors including red, green, blue, and yellow. Most modern amber from the Dominican Republic is golden brown or iridescent blue, depending on whether it is viewed under or against direct sunlight.

Diamond is the hardest natural mineral. It can be colorless, but it is also found in white to blue white, gray, various shades of yellow, brown, orange, pink, red, lavender blue, green, and black. Craftsmen in India used diamonds to drill holes in hard gems like beryl to make beads. Europeans were not aware of India's diamonds until Marco Polo visited the area in the thirteenth century CE. Because diamond forms in a rare igneous rock called kimberlite, its occurrences are limited.

Pearl is composed of the calcium carbonate mineral aragonite produced within the soft tissue of a living shelled mollusk. The highest quality pearls come from the genus *Pinctada*. Pearls are characterized by their translucence and luster with an intricate play of surface colors. The iridescence results from the refraction of light through many layers. The color of pearls varies with the type of mollusk species as well as the water environment it grew in. Pearls can be found in white, yellowish white, pinkish white, bluish

white, reddish, and blackish gray. The earliest use of pearl as a gem appears to be in Europe and dates to the Paleolithic. Freshwater pearls have also been found in rivers in the British Isles and continental Europe. In modern times, saltwater pearls (mostly cultured) are harvested from the northwestern Pacific Ocean, particularly the waters around Japan. The technique for growing cultured pearls was developed by the Japanese in the early twentieth century.

The Bible has over 1,700 references to gems and minerals under 124 Greek and Hebrew names. Many cannot be identified from the biblical text, and others are obscure. One of the most detailed descriptions in the Old Testament is of a breastplate worn by the high priests of the temple; it contained 12 gemstones representing the 12 tribes of Israel. These gemstones were ruby, chrysotile, beryl, turquoise, sapphire, emerald, jacinth, agate, amethyst, topaz, onyx, and jasper. In medieval times these same 12 gems became affiliated with the 12 signs of the zodiac. The modern custom of birthstones is derived from this tradition.

Rocks and minerals that have been altered by humans are found throughout the archaeological record from very early periods (Nassau 1994). For example, the ancient Romans valued darker chalcedony over lighter varieties, and they learned that burning light-colored chalcedony would cause it to darken. Examples of altered color can also be found in obsidian, tourmaline, and sapphire. In dealing with the color of minerals in antiquity, we do not know when early producers discovered that the color of many minerals could be changed by heating; in most cases, methods for heat-treating gemstones became a closely guarded trade secret. Modern technology has provided methods to duplicate natural gems and semiprecious stones (see GEMSTONES); all manner of gem crystals from beads to large pendants can nowadays be produced on a massive scale.

Being able to identify fake gems and semiprecious stones is *theoretically* easy since each has a unique set of physical and chemical properties. The synthetics are designed to have the look and color of a natural gemstone, but most do not have either the chemical or physical characteristics of the natural material. It remains possible to identify the fakes with the proper scientific equipment, particularly optical, but it is difficult

if the only equipment is the unaided eye with a 10-power hand lens, a hardness set of some sort, and a way to measure the density. Highly polished and highly reflecting materials such as gemstones are especially difficult to identify without analytical tools. Artificial gemstones may have a more vivid color than their natural counterparts. Synthetic corundum, including those simulating ruby and sapphire, can be manufactured to have chemical and physical characteristics that are nearly identical to the naturally occurring gemstones.

Rocks are mineral assemblages. They are distinct from individual mineral species and they have played a significant role in the development of society. Lithic resources have been used since our ancestors first threw rocks as weapons and made crude stone tools. Useful rocks are unevenly distributed throughout the world, so trade and exchange developed early. Many distinct properties of rocks can lead to their utilization, that is, hardness, massiveness, convertibility through processing to useful materials (e.g., clays fired to ceramics), and so on.

The Romans discovered that a finely ground mixture of pumice and lime would make a cement that was far superior to lime mortar. It would even set under water (Brandon et al. 2014). Basalt is one of the oldest rock names in use, as well as one of the earliest rocks exploited. It was used for building blocks, monuments, and statues, as well as grindstones, mortars, mauls, and pestles. The term granite refers to a specific type of igneous rock, but also has been used more broadly for igneous building stone. In South America the famous high mountain fortress of Machu Pichu was built largely of granite.

Well-indurated sandstone has been used as a building material since humans first learned how to quarry it. The great pyramid of Cheops at Giza was constructed of limestone, and limestone tools have been made since the Paleolithic. The first use of the term limestone was in the literal sense: a stone from which lime could be extracted (Barba Pingarrón and Villaseñor Alonso 2013). Marble, metamorphosed limestone, has been a major building stone since antiquity, in part because it is softer and much easier to shape than igneous rocks.

Throughout much of the Near and Middle East, where hard rocks are unavailable, clay-based

material has been used for mud brick and related building materials. Most earthen materials are processed mixtures formulated to contain binders, filler, material to control shrinkage, and so on. An important earthen building material is the various forms of rammed earth, including pise and humra.

Dating in Archaeology

KEN MUNYIKWA

Athabasca University, Canada

Introduction

Archaeologists study the lives and activities of humans through the analysis of remains that catalogue that history, and these include fossils, artifacts from occupation sites, and other physical relics. A critical element in such studies is the assignment of a temporal framework to the observed features. More often than not, archaeological materials are found among earth materials. Hence, it is not surprising that dating methods used in archaeology borrow largely from geochronological methods that are used in the earth sciences. The choice of the method that is ultimately employed for any dating exercise is determined by the dating range that is under consideration as well as the types of materials that are available for analysis.

For context, Figure 1 outlines some major milestones of human evolution as well as dating methods that are commonly used in archaeology. It is generally thought that the human lineage diverged from that of chimpanzees around 5–7 million years (Ma) ago or earlier (e.g., Langergraber et al. 2012). Following a number of evolutionary steps (Figure 1), *Homo sapiens* emerged and subsequently spread from Africa into Europe and Asia, starting from around 200 thousand years (ka) ago. By ca. 70 ka, *Homo sapiens* had spread to southeast Asia, reaching Australia around 50–65 ka ago. Humans are only thought to have spread through the Americas after 20 ka. This evolutionary timeline demonstrates that the utility of the dating ranges outlined in Figure 1 varies geographically. When working in Africa, for instance, dating methods that collectively cover all stages of human evolution from around 7 Ma would be expedient. In the Americas, however, methods that only cover the last 30 ka would suffice.

On the basis of their operational principles, dating methods outlined in Figure 1 can be classified into four main categories (e.g., Lowe and Walker 2015). The first group comprises methods that are based on radioactive decay of unstable isotopes. These include radiocarbon, argon isotope, uranium series, luminescence, electron spin resonance and fission-track dating methods. The second category comprises dating methods that are based on pattern recognition, such as annually banded records that can occur in tree rings and lake sediments. The third group consists of methods that use age-equivalent markers for correlating time units. Such markers include stratigraphic indicators that are employed in paleomagnetism as well as layers of tephra from volcanic eruptions. More recently, biological markers have also been used. The final group comprises methods that can only be used for comparative or relative dating. In addition to basic stratigraphic ordering, relative dating methods include chemical dating methods such as obsidian hydration, amino acid geochronology, and fossil bone analysis (Lowe and Walker 2015). Dating can also be performed using chronological typology, which assigns ages to features using physical characteristics associated with societies whose ages are known. The principles behind the methods presented in Figure 1 are briefly outlined below.

Dating methods based on radioactivity

Radiometric dating methods include techniques that compare the abundance of an unstable parent nuclide in a given material to that of the daughter nuclide produced by radioactive decay. Together with the rate of decay, the information is used to determine the amount of time that has passed since the beginning of a particular event. Such methods include radiocarbon (see RADIOCARBON CALIBRATION AND AGE ESTIMATION), argon-isotope (see ARGON-ARGON DATING) and uranium-series (see URANIUM-SERIES) dating methods. Other methods based on radioactivity include techniques that evaluate cumulative

Figure 1 Diagram of the notable milestones of human evolution, as well as the most commonly used dating methods and their applicability in archaeology. Modified after Walker, 2005, p. 14.

radiation damage since the start of a given event. Radiation damage methods include luminescence (see THERMOLUMINESCENCE), electron spin resonance (see DATING AND ELECTRON SPIN RESONANCE (ESR)) and fission-track dating techniques.

Radiocarbon dating

Natural carbon comprises three isotopes: ¹²C, ¹³C and ¹⁴C. Radiocarbon (¹⁴C), which occurs in trace amounts, is unstable and undergoes radioactive decay. In nature, radiocarbon is mostly produced in the upper atmosphere when nitrogen atoms interact with neutrons generated by cosmic rays. The ¹⁴C reacts immediately with oxygen to form carbon dioxide (CO₂) that diffuses throughout the atmosphere. When plant material assimilates CO₂ as part of photosynthesis, it takes up some ¹⁴CO₂. Animals that eat the

plant material also take up ¹⁴C. As a result, the ¹⁴C concentration in all living organisms is similar to that of the atmosphere. When an organism dies, however, it stops taking up ¹⁴C. Hence the concentration of ¹⁴C that it contains begins to decline as the radiocarbon decays. If at any time, a determination is made of what proportion of the original ¹⁴C atoms are still remaining in the organic material, the amount of time that has passed since the organism died can be determined. Radiocarbon years (see RADIOCARBON CALIBRATION AND AGE ESTIMATION) need to be calibrated before they can be compared with calendar years. Archaeological materials that can be dated using radiocarbon include well-preserved organic material such as wood, seeds, charcoal, and bone and other faunal remains. Radiocarbon can generally be used for dating material up to ca. 50 ka old (Ramsey 2008).

Argon isotope dating (K–Ar, Ar–Ar)

Potassium (K) has an unstable isotope (^{40}K) that undergoes a branched decay to yield isotopes of calcium (^{40}Ca) and argon (^{40}Ar). Only the ^{40}Ar branch of the decay is useful for radiometric dating. In archaeology, the dating is usually applied to volcanic rocks that are interbedded with sedimentary units that contain artifacts or fossils. Argon, a gas, escapes when volcanic rocks are molten. When the rocks cool, however, the radiogenic argon is trapped within potassium-bearing minerals. Over time, ^{40}Ar accumulates in the mineral. By measuring the amount of ^{40}Ar , it is possible to estimate the time that has passed since the rock formed (Chernyshev, Lebedev, and Arakelyants 2006). In ^{40}K – ^{40}Ar dating, measurements of ^{40}K and ^{40}Ar are made on separate sample aliquots, which can introduce error when dealing with heterogeneous materials. However, dating using ^{40}Ar – ^{39}Ar (see ARGON–ARGON DATING), which only measures a single aliquot, circumvents the problem. With this approach, the concentration of ^{40}K is ascertained by irradiating the sample in a nuclear reactor to convert ^{39}K to ^{39}Ar . Since the abundance of ^{39}Ar will be proportional to that of ^{39}K , and the abundance of ^{39}K proportional to ^{40}K , a mass spectrometer can be used to determine the ratio of ^{40}K to ^{40}Ar in a single measurement. The much greater sensitivity of ^{40}Ar – ^{39}Ar dating compared with ^{40}K – ^{40}Ar dating allows smaller samples to be analyzed using the former technique. The dating range for argon isotope dating spans from ca. 13 ka to over 4,000 Ma, which makes it a very versatile technique in archaeology.

Uranium-series disequilibrium dating

Isotopes of uranium (^{238}U and ^{235}U) and thorium (^{232}Th) decay through complex decay pathways to give ultimately stable isotopes of lead (Pb). Intermediate nuclides of the decay have a range of differing half-lives, but the overall half-life of each of the chains is too long to be used in archaeological dating. Nonetheless, a useful character of the uranium series decay is that the nuclides tend to behave differently during weathering and deposition, resulting in some of the intermediate nuclides being removed from the decay chains. When such interruptions occur,

the system enters a disequilibrium phase during which radiogenic nuclides start to accumulate anew, providing a mechanism for dating Quaternary events. Materials that can be dated using uranium-series (see URANIUM-SERIES) disequilibrium processes include carbonates extracted from solution, which will be enriched in uranium, for instance mollusks, speleotherms, corals, tufa, and travertines. Phosphates and fossil bone enriched with uranium could also be dated using the same technique. Sediment on ocean or lake floors will be rich in ^{230}Th and ^{231}P and could also be dated using a similar approach. The dating range for the uranium series disequilibrium systems is from ca. 10 ka to ca 1–2 Ma (Lowe and Walker 2015).

Luminescence dating

Luminescence dating is a collective term for dating methods that are based on the ability of some minerals, when subjected to ionizing environmental radiation, to absorb and store energy by trapping electrons in lattice defects. The ionizing radiation emanates from unstable isotopes of the uranium (^{238}U , ^{235}U) and thorium (^{232}Th) decay series as well as from ^{40}K that are in the immediate surroundings of the mineral grains. An additional small component of the radiation comes from cosmic rays. If the minerals are stimulated in a laboratory setting, the stored energy can be released as light and measured. Sample stimulation by heating yields thermoluminescence (TL), whereas exposure to an appropriate optical source gives optically stimulated luminescence (OSL) (see DATING AND OPTICALLY STIMULATED LUMINESCENCE). Dividing the stored energy (paleodose) by the rate at which the ionizing radiation was received (dose rate) allows a luminescence age to be determined (Equation (1)).

$$\text{Luminescence age} = \frac{\text{Paleodose}}{\text{Annual dose rate}} \quad (1)$$

Luminescence dating is generally performed using quartz or feldspar. Both minerals, when exposed to sunlight, are emptied (zeroed) of any previously accumulated energy. Alternatively, the grains could be heated to high temperatures to expel any trapped electrons. Hence, archaeological materials that can be dated using TL

include previously heated artifacts such as fired bricks, fired pottery or terracotta material. Burnt flint or other heated rocks can also be dated. For sediment dating, wind-deposited sand and silt or fluvial deposits that are adequately zeroed can be dated using OSL (e.g., Liritzis et al. 2013). The dating range for luminescence methods is from a few decades to ca. 150–200 ka, although older ages have been reported.

Electron spin resonance dating

In electron spin resonance (ESR) (see DATING AND ELECTRON SPIN RESONANCE (ESR)) dating, as in luminescence dating, ionizing radiation from unstable isotopes of the ^{238}U , ^{235}U and ^{232}Th decay chains, as well as from ^{40}K and cosmic ray radiation, can result in trapped charge in some materials. In this instance, the charge is in the form of paramagnetic electrons that are trapped in crystal defects of mineral grains or other substances. If such materials are exposed to high-frequency electromagnetic radiation within a powerful magnetic field, the trapped electrons become excited. When the magnetic field is changed, the resonance with the excited electrons can be detected. The resonance will be proportional to the number of trapped electrons and is equivalent to the paleodose. The dose rate can be calculated by evaluating the annual dose from the U and Th sources as well as from K and cosmic rays. Thus, the age can be determined using Equation (2):

$$\text{Electron spin resonance age} = \frac{\text{Paleodose}}{\text{Annual dose rate}}$$

Materials that can be dated using ESR include speleothems, corals, tooth enamel, mollusk shells, quartz in rocks and sediments, and burnt flint. Ages from ca. 10 ka up to 2 Ma can be obtained using ESR dating.

Fission-track dating

Radiation damage that occurs in mineral grains containing trace amounts of uranium can result in physical tracks that can be visualized and counted. Such damage occurs when the uranium undergoes spontaneous fission to form elements

of lower atomic number. Fission fragments collide with adjacent atoms of the mineral bearing the uranium, ionizing them to form the damage trails. The tracks can survive in the material for millions of years. Hence, they accumulate over time. By determining the amount of uranium in the mineral grains as well as counting the tracks, the amount of time that has passed since the grain was formed can be determined. Fission tracks are used for dating volcanic rocks such as basalt, tephra, tuff, and pumice. The mineral zircon is usually targeted because it has a high uranium content and is common in igneous rocks. Obsidian has also been used in some studies. Alpha recoil-track dating works on the same principles as fission-track dating, with the exception that the recoil tracks that are counted are produced by alpha particles. Track counting ages can range from ca. 0.1 ka to ca. 2 Ma (Lowe and Walker 2015).

Incremental dating methods

Organisms as well as geological deposits that add an additional feature at regular intervals can be used to measure time. In archaeological dating, tree rings (dendrochronology) and sediment layers in lake deposits have been employed to provide invaluable timescales in some settings.

Dendrochronology

During spring and summer, some tree species add a new layer of tissue for conducting nutrients, following a winter of relative dormancy. The differences in the structure of the layers allow seasonal variations to be recorded as annual sets that can be counted to give age. Oaks and pines are some of the most commonly used species in dendrochronology. Notably, dendrochronology provides floating ages that would need to be pegged to the calendar scale using another chronometer such as radiocarbon dating. For archaeological dating, tree-trunk dating is usually performed on dead or fossil trees that are obtained from sedimentary basins, peat bogs, or archaeological sites. Cross-matching overlapping rings can also be used to extend the chronological

range covered by the tree rings. Dendrochronology produces very accurate ages. Consequently, it has been used to calibrate the radiocarbon scale back to ca. 14 ka (e.g. Reimer et al. 2013).

Varves

Sediment layers in lakes that show annually repetitive depositional cycles are referred to as varves (see *VARVE CHRONOLOGY*). The cyclical nature is usually a product of seasonal variations in the deposits brought into the lake. Dating using varves entails identification of the seasonal layers after which they are enumerated. By correlating ends of different varve sequences, it is possible to link them to create a longer timeline. However, like in dendrochronology, varve sequences form floating chronologies that need to be pinned to the calendar scale using another absolute chronometer. Once calibrated, varves provide very reliable timescales to the extent that they have been used to calibrate the radiocarbon timescale beyond the range of dendrochronology, which currently ends around 14 ka (e.g. Reimer et al. 2013).

Age-equivalent dating methods

Marker horizons that form synchronously across different stratigraphic sequences can be used as benchmarks for estimating ages of other geological units where the markers may be found. Genetic markers of evolutionary change in biological materials can also be used for the same purpose. Temporal markers that can be used for archaeological dating are found in paleomagnetism, tephrochronology, and biological molecular clocks.

Paleomagnetism/archaeomagnetism

The Earth's magnetic field changes over time in both strength and direction. Polarity changes result in the reversal of the magnetic field. When rocks that contain magnetic minerals form, they record these changes in the Earth's magnetic field. Similarly, when archaeological materials including pottery and hearths are heated to high temperatures, they record the Earth's ambient

magnetic properties when they cool. By measuring magnetic properties of well-dated artifacts, an archaeomagnetic record (see *ARCHAEO-MAGNETISM*) can be reconstructed for dating purposes. Archaeological materials from the last 10 ka can be dated using this approach. Magnetostratigraphy (see *MAGNETOSTRATIGRAPHY*) examines the variation of the magnetic characteristics of a sequence of earth materials. Such variations are used for relative dating of rocks, as well as for correlating geological units that formed contemporaneously. Additionally, because polarity reversals are global, when they are dated in volcanic rocks using another dating method such as the argon isotope method, a paleomagnetic timescale can be produced.

Tephrochronology

Explosive volcanic eruptions release material referred to as ash or tephra (see *TEPHRA AND VOLCANIC ASH ANALYSIS*) that can be carried by wind over large distances. When the ash settles on the ground, it creates an extensive isochronous unit that can exceed thousands of square kilometers in area and can serve as a useful stratigraphic marker (Lowe 2011). Tephra units can be dated using absolute dating methods such as radiocarbon or argon isotope methods. Once dated, other geological units interbedded with the tephra that may contain artifacts or fossils can be constrained.

Molecular clocks

Molecular clocks employ rates of mutation in biological molecules (e.g., DNA or amino acids) to estimate time that has passed since the divergence of given biological organisms (O'Reilly, dos Reis, and Donoghue 2015). Importantly, however, the molecular clock is not equivalent to a calendar scale and hence it cannot be used directly as an estimate of time without calibration. Thus, ages obtained using other dating methods are used as benchmarks that allow the rates to be ascertained. The chronological range over which the technique has been used spans from ca. 10 ka to over 600 Ma.

Relative dating methods

The stratigraphic law of superposition is an important principle in archaeological dating. The law states that, for geological units that lie undisturbed, oldest units lie at the bottom and youngest at the top. This allows archaeological materials to be assigned relative ages on the basis of their position in a stratigraphic sequence. In the absence of a distinct stratigraphy, seriation can be used whereby relative ages are assigned on the basis of the frequency of occurrence of cultural artifacts whose ages are known. Natural alteration processes that depend on time can also be used to rank archaeological materials in order of the extent of the change as a means of relative dating. Figure 1 presents three types of such relative dating: amino acid dating, obsidian hydration dating, and the analysis of fossil bone.

Amino acid dating

Most amino acids, the building blocks of proteins, can occur in two forms referred to as isomers. The isomers have similar chemical properties, but when exposed to plane-polarized light, they rotate it in opposite directions, with L-amino acids rotating the light to the left while D-amino acids rotate it to the right. Living organisms only contain L-amino acids. When the organisms die, however, L-isomers are converted to D-isomers until an equilibrium is reached. Thus, by measuring the degree of L to D conversion in a material, a relative age can be estimated. Suitable materials for amino acid analysis include mollusk shells, eggshells and other protein-bearing organic remains (Lowe and Walker 2015).

Obsidian hydration dating

Obsidian is volcanic glass. When exposed to the elements, obsidian absorbs moisture, which results in a hydrated layer referred to as perlite. The thickness of the perlite is partly dependent on the duration of exposure to the elements. Other factors that affect the thickness include the geochemistry of the obsidian, temperature, and humidity. Hence, the utility of the method is mostly restricted to comparing relative ages of

samples from the same site (Lowe and Walker 2015). Archaeological applications of obsidian dating (see OBSIDIAN HYDRATION DATING) have largely been in dating artifacts made from obsidian.

Fossil bone analysis

Fluorine and uranium are elements that preferentially accumulate in fossil bone (see BONES AND IVORY) buried below ground. Although the rate at which the chemicals are taken up by bone is influenced by local factors, it is also time-dependent. This allows fossil bones to be assigned relative ages on the basis of their uranium or fluorine content. In contrast with uranium and fluorine, which increase in buried bone over time, nitrogen in fossil bone decreases as the bone degrades. Hence, by measuring the remaining nitrogen content, it may be possible to assign relative ages to fossil bones, with lower nitrogen content denoting older ages. Fossil bone analysis can be used to compare ages of bones up to 40 ka old (Lowe and Walker 2015).

Diffraction

GILBERTO ARTIOLI

Università di Padova, Italy

Diffraction effects are produced by a crystal lattice through the interference of waves (or particles described as waves following the De Broglie concept of wave–particle duality) having wavelengths compatible with interatomic distances. The effect was first observed by Laue and coworkers over 100 years ago. This seminal experiment demonstrated at the same time that crystals are composed of periodic arrangements of atoms, and that X-rays are electromagnetic waves. Since then crystallographic diffraction techniques based on the interference of X-rays, neutrons (see NEUTRON DIFFRACTION (ND)), or electrons (see TRANSMISSION ELECTRON MICROSCOPY and ELECTRON BACKSCATTER DIFFRACTION (EBSD)) have developed rapidly and become routine tools in the analysis of materials of different nature, including all the natural and human-made materials involved in human activities and forming the archaeological record (see ARCHAEOLOGICAL RECORD) (Artioli 2013). Although commonly used to analyze crystalline compounds, XRD can also be applied to disordered and amorphous compounds producing only diffuse scattering (Guinier 1994). Furthermore, even materials that are normally considered amorphous, such as glass, glaze or glassy materials (see GLAZES, SLIPS, AND PAINTS), may contain a significant number of crystal phases that can yield information on their origin and manufacturing techniques (Artioli, Angelini, and Polla 2008).

Among the variety of techniques presently available for the characterization of materials, diffraction is unique insofar as it is intrinsically sensitive to the ordered (i.e., periodic, symmetric) atomic structure of crystals. Information provided by diffraction techniques include: (1) phase identification and quantification of crystalline compounds and complex polyphasic mixtures; (2) the texture and orientation of crystalline

phases in a material (see METALLOGRAPHY AND CRYSTALLOGRAPHIC TEXTURE ANALYSIS); (3) the atomic and molecular structure of the phases involved; and (4) the physical microstructural state of the material.

Experimentally, the diffraction effects produced by the interference of electromagnetic waves or particle beams with crystalline matter can be directly related to the properties of the crystal phases present in the system (Giacovazzo et al. 2011). The measured sample can be a single crystal (i.e., *single crystal diffraction*), or a large ensemble of crystals (i.e., diffraction from *polycrystalline samples*, or *powder diffraction*) either having the same crystal-chemical nature (monophasic sample) or, more frequently, being a mixture of different crystal phases (polyphasic samples). In all cases, the measured diffraction effects in reciprocal space (or *diffraction patterns*) are interpreted by the simple geometrical relationship described by *Bragg's law*:

$$2d_{hkl} \sin \theta = n\lambda$$

where d_{hkl} is the spacing between the atomic planes in the crystal, λ is the wavelength of the incident radiation, and 2θ is the diffraction angle, that is the angle between the incident beam and the diffracted beam. For any given λ , positive interference (i.e., diffraction) occurs only at the angles satisfying Bragg's conditions for all possible atomic planes in the crystal. Each family of atomic planes d_{hkl} has a specific orientation (defined by the so-called *Miller indices*, hkl) with respect to the crystallographic base vectors, which define the crystallographic unit cell within the periodic crystal lattice.

The investigation of the arrangement of atoms within each crystal phase (i.e., the *crystal structure*) is one of the main tasks of *crystallography* (www.iucr.org). Every solid compound at any given pressure and temperature has a unique crystal structure that minimizes Gibbs free energy, and that it is ultimately controlled by the formation of interatomic chemical bonds. The crystal structure of a solid phase therefore is described by (1) the crystallographic *unit cell*;

(2) the *space group symmetry*; and (3) the type and position of each atom in the unit cell.

Diffraction techniques in essence yield very basic information on the nature of the material, its physical state, and its crystal-chemical arrangement at the atomic and molecular level, providing a means of identifying, characterizing and interpreting crystalline compounds from simple elemental and ionic solids to complex macromolecules. The atomic structures of known crystalline compounds are listed in available databases (ICSD: Inorganic Crystal Structure Database, www.fiz-karlsruhe.de/icsd.html; CSD: Cambridge Structural Database, www.ccdc.cam.ac.uk/products/csd/; MSA-CSD: Mineralogical Society of America Crystal Structure Database, www.minsocam.org/MSA/Crystal_Database.html), and they are essential references for identification and analytical purposes.

Because of the fact that most geological and archaeological materials are polycrystalline and polyphasic, with the notable exception of gemstones (see GEMSTONES), and because of the wide availability of X-ray sources in scientific laboratories, the preferred diffraction technique universally adopted for analytical purposes of geomaterials and archaeomaterials is X-ray powder diffraction (Dinnebier and Billinge 2008). The measured powder pattern (generally described in terms of relative intensity vs Bragg angle or d-space) corresponds to a one-dimensional projection of the reciprocal space, and each measured Bragg peak corresponds to a specific atomic plane within a crystal phase. The analysis of the position and intensity of the peaks allows for straightforward identification and quantification of the crystal phases present in the system. The most complete and advanced method for the modeling and extraction of information from powder diffraction patterns is called *full profile analysis* (or *Rietveld analysis*) (Young 1993).

Modern diffraction techniques applied to heritage materials focus on: (1) *noninvasive measurements*, that is, the analysis of the object without sampling; (2) *2D and 3D crystal phase mapping*, that is, imaging the distribution of crystal phases on the surface or within the body of the investigated objects (also referred to as *diffraction imaging* or *diffraction-enhanced tomography*); and (3) performing *simultaneous and combined*

measurements, in order to provide combined information from diffraction, imaging (see IMAGING) and spectroscopy (see SPECTROSCOPY) on the same sample.

On the one hand, X-ray based diffraction techniques, especially using micro-beams produced by synchrotrons (see SYNCHROTRON-BASED X-RAY ANALYTICAL TECHNIQUES AND MATERIALS ANALYSIS), have the advantage of yielding data with high spatial resolution and low penetration. They are ideal for micro-samples, 2D crystal phase mapping, and surface analysis. On the other hand, neutron beams (see NEUTRON DIFFRACTION (ND)) can be used at low spatial resolution to penetrate thick and dense objects. They are ideal for bulk samples and 3D crystal phase mapping. *Crystallographic texture analysis* (see METALLOGRAPHY AND CRYSTALLOGRAPHIC TEXTURE ANALYSIS) using neutron or high-energy X-ray diffraction has been proposed as a totally noninvasive metallographic method to interpret the manufacturing of ancient metals. Diffraction techniques therefore provide a wide range of powerful tools for investigating all kinds of materials involved in archaeological issues and problems.

Electron Backscatter Diffraction (EBSD)

LUCA PERUZZO

Institute of Geosciences and Earth Resources,
National Research Council, Italy

In the field of heritage studies, a variety of materials may be encountered in different studies concerning art objects, monuments and artifacts in general. Glass, stone, ceramic, mortar, and metal are only a few examples of materials (or part of them) that can have a crystalline nature, matching the basic condition for being analyzed by electron backscatter diffraction (EBSD) (Wanhill 2005; Peruzzo, Fenzi, and Vigato 2011; Gambirasi et al. 2013).

Diffraction of primary electrons of the scanning electron microscope (SEM) beam (see SCANNING ELECTRON MICROSCOPY) can occur when a crystalline material is placed under the beam (Figure 1). Such electrons, diffracted from the lattice planes of a submicron volume of the sample surface, can be collected if a suitable detector (phosphor screen) is placed very close to the sample. Diffracted electrons are intercepted by the screen drawing a pattern of dark and light intersecting lines ("Kikuchi lines"), which represent the crystal lattice geometry. This pattern is characteristic of the crystal structure and orientation of the point it was generated from, thus allowing a precise identification of the mineral phase and its absolute orientation in the space.

The discovery of the physical process on which EBSD is based dates back to 1928, when Nishikawa and Kikuchi recorded diffraction patterns from a calcite crystal on photographic plates and described them as "black and white lines in pairs due to multiple scattering and selective reflection." Over the next decades, several scientists studied this phenomenon, until, in the 1970s, the availability of commercial SEMs allowed great progress in projecting and implementing analytical systems using a phosphor screen and TV camera to record the patterns.

In present-day EBSDs, a high-resolution, high-speed charge-coupled device (CCD) camera is attached to the phosphor screen and connected to a computer-aided system able to rapidly detect and identify Kikuchi lines in EBSD patterns. The acquired pattern is automatically compared to a database of possible phases until a solution is proposed when the best-fitting phase from the database matches that pattern.

Diffraction patterns may be acquired by choosing each single grain, moving the SEM beam from grain to grain; alternatively, data can be acquired on a grid of points over a selected area of the surface of the sample. In both cases, the SEM beam can scan, at high magnification, over a small area of the sample without problems due to the variation of the angle of incidence of the beam with the surface. Conversely, operating at lower magnifications on a large area, the best procedure is to use a stationary beam and acquire the data by moving the sample by means of an automated specimen stage.

The nominal angular resolution limit is approximately 0.5 degrees, and the spatial resolution is related to the resolution of the SEM, which for modern field emission SEMs can be considered to be a few tens of nanometers. Exploiting the ability to scan the beam (or move the stage) over multiple points on the surface, it is possible to easily create an orientation map of a polycrystalline sample, where contiguous points producing similar diffraction patterns are recognized as being part of the same grain. In an orientation map, each differently colored area represents a grain with a distinct crystallographic orientation, allowing boundary characterization, grain size measurements, statistical studies on spatial relations, and preferred orientations quantification (Schwartz et al. 2009).

SEMs are usually equipped with energy dispersive X-ray spectrometry (EDS) systems for chemical analysis (see SEM-EDS AND MATERIAL ANALYSIS). Suitable software enables phases, also with very similar crystal structures but different chemistry, to be differentiated by simultaneously collecting an EBSD pattern and an X-ray

Figure 1 Principle of EBSD pattern formation.

spectrum from each single point on the sample. Thus, EDS data are used to refine the EBSD solution at each point for more accurate phase identification (Nowell and Wright 2004).

Depending on the speed and resolution of the detector, automated pattern acquisition and evaluation is possible at a speed of up to several hundred patterns per second. Patterns can be saved during acquisition, and complete phase identification as well as map reanalysis is carried out offline at an ultra-fast speed of up to several thousand points per second.

These and other technological strengths of the EBSD technique provide powerful analytical tools when applied to archaeological disciplines. Some examples of investigation fields are: characterization of raw constituents and reaction phases originating during the production of materials such as colored, transparent, or opaque glass, mortars (see CEMENTS, MORTARS, BINDERS), and pigments in ceramics and paintings (see CHARACTERIZATION OF PIGMENTS and CHARACTERIZATION OF CERAMICS); study of transformation phases due to deterioration (see DETERIORATION); and analysis of crystallographic texture in metals and alloys (iron, bronze, silver) to infer the manufacturing process (see CHARACTERIZATION OF METALS AND ALLOYS and METALLOGRAPHY AND CRYSTALLOGRAPHIC TEXTURE ANALYSIS).

EBSD mapping, in the case of metal objects, permits a good quantitative representation

of the sample microstructure: a measure of the crystal orientation and angular mismatch between grains, examination of grain morphology, boundaries, and twins, and discrimination between different materials.

Even though EBSD has been widely employed for many years in modern metallurgy to obtain microstructural information from metals and alloys, the application of this technique to ancient metal artifacts is scarce (Zaghis et al. 2005; Mapelli, Nicodemi, and Riva 2007; Barnett, Sullivan, and Balasubramanian 2009). Only a few EBSD-based studies focus on ancient metallurgical processes, so the lack of reference literature and comparison examples is still one of the difficulties of applying EBSD in this research field, and this needs to be further explored.

As previously mentioned, another challenging aspect of EBSD is the possibility to identify unknown mineral phases discriminating among different but similar compounds. Phase identification obtainable through EBSD is often impossible to achieve by other methods such as X-ray diffraction, wavelength dispersive spectroscopy, and transmission electron microscopy, and, keeping in mind that samples coming from works of art are frequently unique or extremely small, limitations can be due to different reasons, which frequently coexist, mainly: (1) the particles to be analyzed are too small; (2) the particles are too few; (3) the particles are intrinsically dispersed

in a complex texture and do not provide a recognizable signal, or they cannot be separated and concentrated; (4) chemistry does not allow discrimination between different minerals having similar composition; and (5) other technical difficulties in performing and/or interpreting analyses (for example, X-ray shielding caused by lead-based materials). Such restrictions can frequently be overcome by using the EBSD technique because the diffraction signal is produced by particles even smaller than 1 micron, which can be appropriately observed and identified by conventional SEM backscattering imaging.

Some limitations of this technique are commonly recognized and can be summarized as follows: The best rate of diffracted electrons is obtained for a particular beam/surface geometry so that the sample has to be tilted at nearly 70 degrees, placing the phosphor screen very close to the sample. Operating at a working distance usually in the range 5–25 mm, the possibility of collisions is strongly increased due to the reduced distance between the sample, phosphor screen, and other detectors.

Among other minor technical problems that can arise during the experiment, it is well known that the polishing of the specimen represents a decisive step in the preparation of samples. In fact, a perfectly smooth surface is needed to produce a pattern sufficiently sharp enough to be indexed, especially in the case of automated acquisition and indexing, so careful sample preparation is crucial to achieve successful EBSD analysis. Electro-polishing, and chemical and ion etching are good techniques used to remove any remnant deformation layers and surface irregularities, but for rock-like materials (mortar, stones, pottery, glass, etc.), sample preparation usually consists of many mechanical grinding and polishing steps of the sample surface. After mounting in epoxy resin, the sample is usually ground by means of a vertical diamond wheel, in order to obtain a rough flat surface, and then smoothed by an automated polisher. As grit-based polishing always introduces huge lattice distortion in the uppermost crystal surface, this damage must be definitely removed to obtain quality patterns. The first fine polishing is achieved by successively polishing using 6- to 1-micron-size diamond suspensions on silk cloths for a few minutes each.

Finally, the specimen is polished by means of a vibrating polisher with colloidal silica, for time periods that basically depend on the nature of the sample—ranging from a few minutes in the case of soft metals such as copper, to several hours for hard minerals like quartz and silicates in general.

With inhomogeneous materials, differences in strength between particles and the surrounding matrix could cause an imperfect polishing of some crystal surfaces. This happens, for example, in the case of mortars and plasters where hard mineral grains (quartz, silicates, etc.) are enveloped in a relatively softer carbonate matrix. Due to this difference in strength, during polishing, soft material tends to be mostly removed in respect to the harder grains that remain as reliefs on the surface. When the sample is tilted at a high angle, the surface topography enhances the interference with the incident beam, causing shadowing effects and electron charging.

Similar difficulties can occur in the study of alteration products caused by material deterioration or reaction rims grown during production processes (melting, precipitation, etc.) where softer substances are in close contact with harder ones.

In the frequent case of insulating materials, conductive materials such as carbon and gold can be sputtered or evaporated onto the sample to avoid charging effects. The coating should be as thin as possible, but sufficient to dissipate the electron charge on the surface without reducing the signal of diffracted electrons emerging from the sample. A range of 3–5 nm is generally acceptable for EBSD, although reasonable quality EBSD patterns have been obtained while operating in low-vacuum conditions without coating.

The Encyclopedia of Archaeological Sciences: Bridging Archaeological Scholarship and Science

SANDRA L. LÓPEZ VARELA

Universidad Nacional Autónoma de México

Archaeological investigations have become increasingly sophisticated in recent decades with the application of analytic methods to the study of past and present societies. The application of analytical methods to interpret material remains and to learn about human populations from the distant past to the present has encouraged the collaboration of archaeologists with scientists from a wide range of disciplines. The collaboration has resulted in numerous peer-reviewed publications, in new lectureships and professorships, in a wider range of undergraduate and postgraduate degree courses being offered, and even in dedicated funding by research entities.

However, learning about the compositional structure of archaeological materials or surveying sites with sophisticated tools requires a more rigorous interpretation of archaeological data: it involves reasoning with a theoretical background in a wide range of disciplines from the humanities and the social sciences. In an unprecedented effort, the Society for Archaeological Sciences (SAS) and Wiley Blackwell came together to provide the reader with an essential reference work from which to learn about the epistemic challenges behind the use of science and technology in the field and the laboratory, and to interpret social contexts and individual actions.

The Encyclopedia of Archaeological Sciences is a four-volume print and electronic multidisciplinary reference work, comprising more than 480 entries, written by more than 550 contributors from 47 countries. It covers essential content areas, offering a detailed

description of analytical methods and case studies through the many voices of archaeologists, heritage practitioners, and scientists around the world. How we reason with science and technology to learn about societies in the past and the present is what distinguishes this reference work of value to these professionals and students of archaeology and related disciplines. To support its aim, *The Encyclopedia of Archaeological Sciences* includes key theoretical concepts to provide evidence and solutions to approach the diversity and complexity of human societies through time. Therefore, scholars from the social sciences and the humanities have joined us in this venture, highlighting the value of archaeological data in providing innovative approaches and solutions to modern phenomena that are challenging our capacity to live on the planet.

Archaeological Sciences

Archaeology, defined generally as the study of societies in the past though the analysis and interpretation of material remains, is a discipline in which practice is entwined with the history of science. Many scholars have written about the history of archaeology, from Glyn Daniel (1981) to Bruce Trigger (2008) and Tim Murray and Christopher Evans (2008). All of them have inspired this brief history of the relationship between archaeology and science, resulting in the founding of archaeological sciences, a sub-discipline generally interested in the application of science, technology, engineering, and mathematical methods in archaeology, as expressed by Dr. Martín-Torres in this volume. In this overview of its history, I discuss the fact that this science-based archaeology is inspired by a theoretical background, and, as such, it is central to the formulation of new theories by providing insights to long-standing assumptions in archaeology (see Martín-Torres and Killick 2015).

Archaeology, Science, and Philosophy

The scientific principles that established archaeology as a discipline in the nineteenth century may be traced to that moment in our history, back in the seventeenth century, when science replaced Biblical explanations through the works of Descartes, Bacon, Newton, Leibniz, Galileo, and John Locke. The “Age of Enlightenment,” as referred to by Immanuel Kant, was simply the period when the explanation of natural and social phenomena was based on human observation and experience. The search for explanations invited scholars, such as William Harvey and John Aubrey, to conduct explorations at Stonehenge and Avebury in England, respectively.

During the eighteenth century, human reasoning dominated many disciplines, including philosophy, mathematics, and astronomy, paving the way for the establishment of new fields of knowledge that incorporated earlier inventions, such as the microscope and the telescope, to fortify their observations. Knowing about the past was of great interest to monarchs and was also a means to gain fame and prestige. What could now be understood as “state-sponsored excavations” resulted in the exploration of Pompeii and Herculaneum, funded by Carlo di Borbone. In 1764, the advent of archaeology as a discipline was outlined in the publication *Geschichte der Kunst des Alterthums*, in which Johann Joachim Winckelman presented a systematic approach to the study of the past by separating and classifying Greek from Roman art at the end of the eighteenth century.

In the nineteenth century, explorers introduced a fundamental change to research practice by going into the “field.” Knowledge based on “fieldwork” was of ultimate importance to great explorers such as Alexander von Humboldt and Charles Robert Darwin. The five-year exploration of the Americas by Humboldt was not only crucial to the natural sciences, but also to archaeology and anthropology, as he recorded the antiquities of the New World and its people. “Fieldwork” observations were crucial to Lyell’s relative dating of geological strata, suggesting that upper soil horizons were newer than the lower ones. Lyell’s research introduced its first dating method to archaeology. In my own personal opinion, these centuries are unique in the sense that the natural

sciences and the humanities had never worked so closely together to expand human knowledge.

Throughout the nineteenth century, professional societies were established, and universities around the world began offering specialized degrees in a wide range of disciplines. Natural scientists advanced their observations by developing theories and methods based on laboratory practice. In fact, the Rathgen Research Laboratory, created in 1888, was the first of its kind to conduct chemical procedures for the preservation of objects housed at the Royal Museum in Berlin, now the *Altes Museum*. What an honor it is to have Dr. Stefan Simon, who was director of the “Rathgen Lab” between 2005 and 2014, as one of our contributors.

Darwin’s theory of evolution and its application to understanding societies were two essential principles guiding Augustus Pitt Rivers to create typological classifications to establish chronological sequences. His systematization of artifact studies, together with Mortimer Wheeler’s introduction of the grid system, set the basis for considering archaeology as a scientific activity.

During the twentieth century, quantum physics and the theory of relativity brought important changes to the construction of knowledge by investigating phenomena through observable, empirical, and measurable evidence from which theories can be extracted and tested with hypotheses. Archaeologists adopted these scientific principles, acknowledged as positivism, in the 1960s, after archaeological research moved away from a cultural historic approach, defining societies based on their ethnicity and material culture. The introduction of the electron microscope and the early definition of DNA are just a few examples of the new technologies and research that influenced archaeological research. However, one of the most important discoveries of great impact on archaeology after World War II was the introduction of radiocarbon dating by Willard Libby. In 1946, Libby proposed the dating of organic materials by measuring their content of carbon-14. Radiocarbon dating now uses other methods beyond measuring decay rate, explained here by Dr. Ramsey, Director of Oxford Radiocarbon Accelerator Unit.

From Archaeometry to Archaeological Sciences

In outlining the history of archaeology and science, Oxford University has played an important role. In 1958, Prof. Christopher Hawkes coined the term “Archaeometry” as the new title of the *Bulletin* published by the Research Laboratory of Archaeology and the History of Art at Oxford University, still published by Wiley Blackwell. The *Bulletin* described the applications of the physical sciences to the study of the past at this facility. Described in these pages by Prof. Michael Tite, “archaeometry” is now a more or less obsolete term, making reference to the study of artifacts and buried archaeological features by physical and dating methods. Still, the International Symposium on Archaeometry, owing its existence to Dr. Martin Aitken, who was also director of this lab and one of the greatest scholars archaeology has ever seen, uses this word. This international symposium began as a day meeting organized by Dr. Aitken back in 1962. The meeting became the “Symposium on Archaeometry and Archaeological Prospection” in 1969. In 1976, it changed its name to the “International Symposium on Archaeometry and Archaeological Prospection.” Since 1980, the International Symposium on Archaeometry has been a specialized forum for all those using scientific techniques for the extraction of archaeological and historical information.

The post-World War II era created a context that questioned the “philosophy” behind previous scientific practices, resulting in novel approaches involving the social sciences and the humanities. The “new philosophy of science” offered an interdisciplinary knowledge-trading zone between the natural and the social sciences that reached archaeology in the 1970s. Archaeology, a discipline then dedicated to the study of past “civilizations” through their material remains, became interested in learning about societies, entangled in a network of social, political, and economic variables. Archaeology required new tools and theoretical paradigms from other disciplines, including environmental sciences, biology, computing, and mathematics, to approach new questions—questions that archaeometric studies could not address entirely. Consequently, the word “archaeometry” does not express the

wide range of disciplines used in archaeological research today. Therefore, the term “archaeological sciences” is more appropriate to make reference to the application of science, technology, engineering, and mathematical methods in archaeology, as discussed in this reference work by Dr. Martín-Torres.

The expansion of scientific techniques applied to archaeological research laid the groundwork for the organization of the Society for Archaeological Sciences (SAS) during the International Symposium on Archaeometry and Archaeological Prospection that took place at the University of Pennsylvania in Philadelphia in 1977 (Sternberg 2014). The SAS, as a professional society, is interested in advancing archaeological sciences and promoting an active program encouraging interdisciplinary research in archaeology (Sternberg 2014). Since 1977, the SAS has published a *Newsletter*, now the *Bulletin*, as part of its strategies for communicating with its membership. Since 1982, the SAS has sponsored archaeological science sessions at the Society for American Archaeology. The SAS is committed to rewarding outstanding students through the R. E. Taylor Poster Award and supporting their research activities through the SAS Student Research International Travel Award. The SAS is one of the few professional organizations in archaeology whose leadership has been in the hands of foreign scholars, such as myself.

For the SAS, archaeological sciences embrace much more than the physical, biological, chemical, and environmental sciences, by studying organic and inorganic archaeological remains and their spatial location, aided by computing and mathematics to process, analyze, model, and predict derived data. The close engagement with scientific disciplines and correlated methods is simply to learn about human societies in the past and in the present. In fact, *The Encyclopedia of Archaeological Sciences* was designed to inform analytical methods with a larger corpus of interdisciplinary theories to understand human societies in the past and the present. Conceptual frameworks from other domains in anthropology, ethics, economics, history, political science, and aesthetics, to mention just a few, interact throughout this reference work, with the use of science and technology to answer questions about the past and the present.

The Encyclopedia of Archaeological Sciences: An Introduction

In 2011, as I ended my term as President of the SAS, Wiley Blackwell supported my interest in developing *The Encyclopedia of Archaeological Sciences* (EAS), a reference work for those interested in learning about the application of science and technology in archaeology. In heading this project, I envisioned an encyclopedia of archaeological sciences establishing a dialogue between archaeological theorists and archaeological scientists, given the unnecessary and unproductive existing division between these “two cultures,” which Martínón-Torres and Killick (2015) have discussed so eloquently.

In building the contents of the EAS, I invited 10 international and well-recognized scholars, who have different professional backgrounds, to manage key areas and to provide the reader with the scientific principles and techniques to understand the lives of those who have come before us, supported by theoretical approaches from the social sciences and the humanities, to allow for a more rigorous interpretation of archaeological data. In asking myself about the future of archaeological data, part of the vision of the EAS had to include key areas showing us how to take care of our past and to find good practices to preserve our past for future generations. In my capacity as a Humboldt Foundation fellow and prize awardee, I have met scholars from a wide range of disciplines through multidisciplinary international forums, in which we all have demonstrated the value of our disciplines and of facing, together, current phenomena challenging our living in this world. The EAS aims to demonstrate, to professionals and practitioners from those disciplines from which we have borrowed, what archaeology has to offer in analyzing and solving current natural and social phenomena. The contents of the EAS, therefore, lay bare my concerns.

The Structure of The Encyclopedia of Archaeological Sciences

Concerned about the growing educational and professional needs in the field, the EAS was divided into 11 essential and interrelated content areas or sections, from which headwords were

developed by the associate editors. Together with Dr. Gilberto Artioli, we defined headwords describing the fundamentals of scientific principles and techniques that were presently used in archaeology or could be of use to future research. Therefore, the user of the EAS will be able to learn the workings of a specific technique in great detail. The section provides a background for learning about the application of these techniques in the field and the laboratory for analytical or conservation purposes. In working together with Dr. Christian Wells, we identified those techniques that help professionals survey and excavate a terrestrial or underwater site. In dating archaeological findings, Dr. Josep Parés followed simple questions to build his section. How do we construct time in archaeology and which techniques are of use to date archaeological findings? How we study and characterize archaeological materials and how artifacts were made are some of the questions that Dr. Luis Barba followed to build a section that could be the basis for understanding the technology behind the making of an object and the reasons why an artifact was made. The question of who made those artifacts required an understanding of people in the past. In approaching how to study people in the past, Dr. Lori Wright and Dr. Kristin Hoffmeister developed a section to help us define population genetics, age, and gender, and even their diet and mobility. Mrs. Gill Campbell, through her section, has supported our interest in reconstructing people's natural living environment and in understanding the subsistence and economic activities that formed part of their landscape.

Working with archaeological data to interpret past societies involves reasoning, not only based on theories; it involves mathematics, logic, statistics, and modeling. How to construe archaeological data as evidence of past societies requires well-structured research, based on a hypothesis and an understanding of the validity and reliability of our data. Which kinds of techniques or instruments can help us compute these data? These questions, developed by our contributors, have the intention of pursuing social interpretations from numbers. Encouraging social interpretations of instrumental results involves theoretical approaches that Dr. Julian Thomas has carefully selected to help us reason

with science, inviting us to rethink how we build our knowledge about the past from the present.

How to visualize and analyze archaeological data has been the task of Dr. Christopher Dore, who has brought together a group of scholars sharing their expertise in creating images through analytical instruments, augmented reality, or 3D imaging, along with the use of information and communication technologies (ICT) to facilitate archaeological research and disseminate its results. How to preserve the past is a key concern of the EAS. Conservation is the obvious answer that Dr. Ioanna Kakoulli provides, by sharing with us those techniques and best practices to help us extend the life of excavated or stored artifacts through the words of her contributors. What to preserve and how we connect with the past are key concerns approached by Dr. Graham Fairclough and his contributors. The value of heritage to society is included in the EAS, introducing the reader to different heritage management preservation strategies.

The Encyclopedia of Archaeological Sciences is simply the result of the Associate Editors and its contributors, who kindly collaborated with us and helped us build the headwords that make this reference work possible. Indeed, we need to accept that we might be missing some key concepts. Like any long-term project, we added new key concepts, while we had to drop others for various reasons. The Associate Editor and the Editor-in-Chief, working hand in hand with the contributor, reviewed each submission. In some cases, external peer-reviewers revised some of the entries for final acceptance.

I asked the Associate Editors to invite well-known scholars to write the entries. To me personally, it was very important to invite those scholars who do not publish regularly in English and, therefore, are less known to our community. In addition, I wanted to invite new talents and to give them the opportunity to publish along with our well-established scholars. In the end, we recruited over 550 contributors from 47 countries, not all English native speakers, including myself. Their participation has given us the opportunity to include multiple perspectives and case studies from around the world. I could not be more indebted to all of our participants and our editorial staff for their willingness to collaborate in our project.

How to Use *The Encyclopedia of Archaeological Sciences*

The EAS aims to be a basic source for archaeological research through a compendium of terms, covering the specifics of a technique, how the technique is used in archaeology, and how we can construe its results as evidence to learn about societies in the past or even in the present. This may be achieved by searching terms linked across areas of interest. In addition, each term, generally, has a further reading section to expand coverage, in case the reader would like to know more about a particular area. Given the nature and range of its contents, the EAS stands as a reference for the expert who wants a quick source of details about a specific technique or theory.

In building the contents of the EAS, I envisioned its use in the classroom and as an aid in building lesson plans. Therefore, I encourage those teaching courses in a diverse set of classrooms, not only those related to archaeology or anthropology, to use the EAS as a source for students to learn about a term and to encourage discussion surrounding its application and to learn about societies in the past and in the present.

Why Now is the Perfect Time to Publish an Encyclopedia of Archaeological Sciences

In the twenty-first century, archaeology can no longer be conceived without science, or at least, this is what our generation learned back in the 1980s, when many of us were trained to combine anthropology, archaeology, materials sciences, and spatial analysis to approach societies in the past. Many scholars from this interdisciplinary generation have extended archaeological practice to those working with environmental and social sustainability and to approach global challenges, such as climate change, ocean health, poverty, food security, energy, even human rights and democracy. Until very recently, such collaboration was a source of optimism for our collective future.

Across the globe, scientists have detected a decline of trust in science and scholarship, given the unsubstantiated assertions released through

public discourse and disseminated by mass media. In this setting, we should ask ourselves why unsubstantiated assertions are gaining more attention from the public than evidence-based argumentation. The publication of *The Encyclopedia of Archaeological Sciences* comes at a time when we need to acknowledge our shared responsibility to society and analyze the ways we communicate our research results to the average citizen, if we wish to reverse this situation. The EAS has built a vibrant international community standing up strongly for science, the social sciences, and the humanities, regardless of the political winds trying to set up barriers between countries. The EAS advocates for science, through the diversity of voices unified here, as a building force, contributing to world prosperity and peace.

Gas Chromatography-Mass Spectrometry (GC-MS)

ERIKA RIBECHINI and MARCO MATTONAI

Università di Pisa, Italy

Gas chromatography-mass spectrometry (GC-MS) is a hyphenated technique: a combination of two techniques used to study and characterize mixtures of organic molecules. Gas chromatography separates the organic molecules of a mixture, and mass spectrometry characterizes each molecule. By combining the two techniques, organic samples can be both qualitatively and quantitatively evaluated.

GC-MS is one of the preferred analytical approaches used to characterize organic substances and materials from archaeological findings, as confirmed by a number of successful applications and case studies reported in the literature (Colombini and Modugno 2009; Colombini et al. 2010; Colombini, Modugno, and Ribechini 2012; Bonaduce et al. 2016). GC-MS is unique in its ability to yield complete chemical structure assignments and to identify a great variety of organic substances, thus enabling characterizations at a molecular level to be carried out. The most common application of GC-MS in archaeology is the identification of molecules that behave as markers (Colombini, Modugno, and Ribechini 2005; Evershed 2008). The key idea behind the concept of *biomolecular markers* in archaeology is that the carbon skeleton of some organic molecules remains fundamentally unchanged during aging, while the main transformations affect the functional groups. By identifying the structure of the organic components of the sample (or *analytes*), it is possible to establish a “product–precursor” correlation and hypothesize the original molecular structures. If these molecules are unique to a certain material, they can then be used as *biomolecular markers*

to establish the origin of the natural substances present in the sample, and to understand the natural and artificial alteration processes that modified the materials.

Gas chromatography (GC) is an instrumental technique that allows the separation of the different components of a sample (see CHROMATOGRAPHIC TECHNIQUES IN CONSERVATION AND CHROMATOGRAPHY AND ARCHAEOLOGICAL MATERIALS ANALYSIS). The molecules are carried, or *eluted*, by a gas (typically He, N₂ or H₂) through a capillary column. Modern GC columns are typically 15–60 meters long, with a submillimetric diameter. The external part of the column, which is flexible and inert, is usually made of fused silica. The inner wall, which is in contact with the carrier gas and the sample molecules, is coated with a uniform film of polymer, which can be functionalized to increase the separation efficiency towards specific classes of compounds. The carrier gas is also called the “mobile phase”, while the internal coating polymer is called the “stationary phase”.

GC analyses require the samples to be in the gaseous phase. The introduction of a sample (in liquid or gaseous phase) into the GC instrument is called *injection*, since it is usually performed with a syringe. The *injector* connects the entrance valve with the chromatographic column. This is also the place where the volatilization of liquid samples takes place. Injection is a very delicate part of the GC analysis. GC injectors are equipped with a *gas-split* system, which reduces the amount of injected sample that actually reaches the column.

The *split ratio* is a very important parameter that indicates by how much the sample quantity will be reduced. Split ratios can be as high as 100:1 (i.e., only 1 percent of the injected sample will be analyzed). A high split ratio is particularly useful when dealing with highly concentrated samples, for which even the smallest injected quantities are excessive. When dealing with very diluted samples, on the other hand, the gas splitter can be shut off, and the injection mode is called *splitless*.

Inside the column, the molecules are separated according to their volatility. Lighter molecules,

with a lower boiling point and a greater tendency to remain in the gas phase, will quickly reach the end of the column, while larger molecules, with higher boiling points, will require more time. Since the volatility of a molecule is directly correlated with the temperature, the column is coiled inside an oven. The temperature is accurately monitored during the analysis, and is usually increased over time (usually with rates between 5 and 20°C min⁻¹) in order to increase the volatility of the heavier molecules. Temperatures in the range 50–300°C are typically used.

Once the molecules are separated by GC, they are identified using a mass spectrometer (MS) (see MASS SPECTROMETRY (MS)), which is directly connected to the end of the column. Inside the MS, the molecules are converted into ions in gaseous phase by ionization techniques, the most common being collision with a high-energy electron beam generated by a metal wire held normally at 70 eV. A molecular ion is initially generated by removing one electron from the molecule, as shown in reaction (1). This molecular ion is energetically unstable, and undergoes fragmentation and rearrangement reactions to generate smaller ion fragments.

Inside the mass spectrometer, the ions are separated according to their *mass-to-charge ratio* (*m/z*) values. The piece of instrument that separates the ions is called a *mass analyzer*. There are several types of mass analyzer, based on different principles and with varying performances. The most common mass analyzers are quadrupoles (Q) and ionic traps (IT), which analyze the ions by applying electromagnetic fields. Once the ions have been separated by the mass analyzer, their amount is calculated by a detector. The detector, typically an electron multiplier, records the ionic current produced when an ion passes by or hits a surface.

The final result of the analysis is a *chromatogram*, which is a graph that shows the intensity of the ionic signal (the current) as a function of time. A mass spectrometer can work both in TIC (total ion current) and SIM (single ion monitoring) acquisition modes. When TIC mode (known also as *full scan* mode) is used, a range of *m/z* values is monitored and acquired. A typical mass

scan range covers from 50 to 700 *m/z* values. In SIM mode, only a few *m/z* values, typically two to four, are acquired. The use of SIM improves selectivity and sensitivity, and consequently the SIM mode is frequently used for quantitative GC-MS analyses. On the other hand, the TIC mode is preferred for qualitative analyses and for identifying unknown compounds. The type and number of ion fragments obtained during ionization are reproducible and characteristic of each molecule, and thus a mass spectrum can be used as a *fingerprint* for its identification. In addition, the area of the chromatographic peak is directly proportional to the concentration of the corresponding species in the sample, thus enabling a quantitation of the sample components to be carried out. The proportionality constant for the conversion is usually determined by performing a GC-MS analysis of a sample in which the compound is present at a known concentration.

In the archaeological field, GC-MS has been used to characterize different types of samples, such as resins, lipids, waxes, and proteins (Bonaduce et al. 2016; Colombini and Modugno 2009; Colombini et al. 2010, 2012) (see PIGMENTS AND BINDERS). A number of challenges must be overcome when searching for markers. For example, biomarkers can be trapped inside the matrix by physical and/or chemical interactions with the other constituents of the sample. Moreover, some of these markers cannot be directly analyzed with GC-MS, since their dimensions and chemical structures make them nonvolatile. A pre-treatment of the sample is thus required in order to isolate the compounds of interest from the matrix and to transform them into species that are suitable for GC-MS analysis.

Isolation techniques include: (1) *liquid-phase extraction*, which can be used to separate compounds with significantly different polarities; (2) *sonication*, which can overcome the physical trapping of the molecules by decomposing the matrix and improving the efficiency of liquid extraction; and (3) *solid-phase extraction*, which can also be used to pre-concentrate the analytes.

Transformation techniques include:

1. *Hydrolysis*, which is the breaking of chemical bonds by reaction with a water molecule.

Hydrolysis can be used to decompose polymeric species such as proteins and polysaccharides (present in animal proteins and plant gums as pigment binders; see PIGMENTS AND BINDERS) into their monomers, as well as to obtain free fatty acids from mono-, di- and triglycerides (the main constituents of acylglycerolipids such as plant oils).

2. *Derivatization*, which is the reduction of the polarity of molecules by modifying their functional groups. This is done by reaction of the analytes with a *derivatizing agent*, which increases their volatility. Derivatization typically affects functional groups that have mobile hydrogen atoms such as hydroxyls and carboxyls, since they are the most polar.

Table 1 lists the pre-treatment steps usually required for the analysis of organic species commonly found in archaeological samples. The table also shows the molecules that are obtained at the end of the pre-treatment and are detected by GC-MS. A derivatization step is required in all cases, since hydroxyl and carboxyl groups can be found in all analytes. Polar groups are known to interact with the solid phase of the column, generating broad and poorly resolved peaks in the chromatograms. Derivatization thus also improves the quality of the chromatograms.

Typical derivatization reactions are methylation and silylation. With methylation, mobile hydrogens are replaced with methyl groups. This reaction is usually performed with tetramethylammonium hydroxide (TMAH). With

silylation, mobile hydrogens are replaced with silicon-based groups such as trimethylsilyl ($\text{Si}(\text{CH}_3)_3$). This reaction is usually performed with bis-trimethylsilyltrifluoroacetamide (BSTFA). Examples of methylation and silylation reactions of carboxylic groups are shown in reactions (2) and (3), respectively.

A practical case study is now presented for the data and results obtained in the GC-MS analysis of a sample collected from a Roman amphora found in an archaeological site where several Roman ships were uncovered (Pisa, Italy). In Roman times, ceramic amphorae were usually coated with resinous substances in order to make them waterproof. Among the various substances that can be found in archaeological samples, resins are of particular interest, due both to their wide use as a multifunctional material, and their stability toward aging. The main chemical components of resinous materials are terpenes, which comprise a vast family of compounds originating from the combination of two or more isoprene molecules. Pine resin was a very common material in ancient times, and was frequently used for the production of pitch (Colombini et al. 2003, 2005; Duce et al. 2015). The most abundant terpene in pine resin is *abietic acid*, whose structure is shown in Figure 1a. When

Table 1 Pre-treatment steps and expected analytes for the GC-MS analysis of organic materials of archaeological interest.

<i>Material</i>	<i>Pre-treatment</i>	<i>GC-MS analytes</i>
Proteins	Isolation from matrix, hydrolysis, derivatization	Amino acids
Polysaccharides	Isolation from matrix, hydrolysis, derivatization	Monosaccharides
Acyl-glycerolipids	Saponification, liquid-phase extraction, derivatization	Fatty acids
Waxy lipids	Saponification, liquid-phase extraction, derivatization	Long chain alcohols, hydrocarbons, fatty acids
Resins, pitch and tar	Saponification, liquid-phase extraction, derivatization	Terpenes

Figure 1 Reaction schemes for the oxidation (a) and the heating (b) of abietic acid. TIC chromatograms of the acidic (c) and neutral (bottom) fractions (d) of an archaeological pine pitch sample. MDA, methyldehydroabietate; DDA, didydroabietic acid; DA, dehydroabietic acid; 7-ODA, 7-oxodehydroabietic acid; RET, retene; SIM, simonellite; MRE, methylretene.

pine resin is subject to aging, abietic acid undergoes oxidation reactions, leading to the formation of dehydroabietic and 7-oxodehydroabietic acid. When the resin is heated to generate pitch, on the other hand, abietic acid loses the carboxyl group and undergoes a series of dehydrogenation reactions, producing norabietatriene and retene (Figure 1b).

The different products of these two reaction pathways can be used to distinguish archaeological samples containing pine pitch from those containing pine resins. This is done by performing a liquid-phase extraction to separate the neutral components (norabietatriene and retene) from the acid ones (abietic acid, dehydroabietic acid, 7-oxodehydroabietic acid).

The two fractions are then analyzed separately by GC-MS. If the neutral compounds are present, the archaeological sample probably contained pitch, while if they are absent, it probably contained untreated resin.

Figures 1c and d show the chromatograms of a sample collected from a Roman amphora found at the site in Pisa. The chromatogram of the acidic fraction shows clear peaks corresponding to dehydroabietic and 7-oxodehydroabietic acid, as well as a signal for didehydroabietic acid, which is an intermediate species between the two. The neutral fraction, on the other hand, shows signals corresponding to retene, methylretene and simonellite (an isomer of methylretene). The presence of methyldehydroabietate is particularly interesting. This compound originates when pine resin is heated in the presence of wood. From these data, we can hypothesize that the amphora probably contained pine pitch, and that this pitch was produced by directly heating the resin on the wood.

A separate discussion is required for a specific pre-treatment technique: *pyrolysis*. Analytical pyrolysis is the thermal degradation (generally in a temperature range between 300 and 800°C) of a sample into molecules (pyrolysis products or fragments) of lower mass, yet large enough to provide analytical information on the original sample. Given that these smaller compounds are more volatile, they can be analyzed by GC-MS. The pool of pyrolysis products observed then provides a fingerprint of a particular sample, in terms of both fragment nature and relative distribution. The data output of the analysis is a *pyrogram*. Modern analytical pyrolysis instruments provide a good reproducibility of the results. One of the main advantages of pyrolysis is that it requires no sample pre-treatment. Solid or liquid samples can be placed directly inside the pyrolyzer, the chamber in which the pyrolysis takes place. The pyrolyzer is usually equipped with a needle directly inserted into the GC injector, and the whole technique is known as Py-GC/MS.

Pyrolysis thus has a similar purpose to hydrolysis, but is preferred when dealing with very stable compounds, especially natural polymers, which are hard to pre-treat by wet chemical methods before GC-MS analysis. Classic examples of such compounds are *fossil resins* such as ambers and

lignin, one of the major components of wood. Lignin is more stable towards aging than other wood components, and therefore its analysis is of great interest in the archaeological field. Lignin is a polymeric compound, but its chemical bonds are very stable and hard to break using hydrolysis. Pyrolysis is a very effective way to analyze wood samples with GC-MS (Colombini et al. 2012; Lucejko et al. 2015).

Geoarchaeology

CRISTIANO NICOSIA

Università degli Studi di Padova, Italy

Introduction: Geoarchaeology is Archaeology

Two recent publications (Hill and Rapp 2010; Hill 2017) have thoroughly and exhaustively described the history of geoarchaeology. The latter will not therefore be recalled in detail here. Still, a brief focus on the initial or “formative” stage of the collaboration between earth sciences and archaeology, around the middle of the nineteenth century, will be provided. This phase can be summarized in two main epistemological trajectories. On one side, there is the research concerning the “antiquity of man.” On the other side, the circumstances that led to the “birth of interdisciplinary archaeology.” More than archaeologists, it was early “earth scientists” or “natural scientists” such as C. Lyell, J. Boucher de Perthes, and W. Pengelly who dealt with the issue of the antiquity of man. These scholars were primarily interested in demonstrating the unequivocal association of remains of long-extinct fauna with objects produced by man. To achieve this incontrovertible and scientific evidence, *stratigraphy*, was employed as key method, and the *stratigraphic* excavation of Brixham Cave (Devon, UK) by Pengelly in 1858–59 led to the general acceptance—also favored by the publication in 1859 of Darwin’s *On the Origin of Species*—that indeed man coexisted with (Pleistocene) extinct fauna and therefore existed prior to the biblical deluge. The close ties between geology and cave and rock shelter archaeology or, more broadly, Paleolithic archaeology, begun here. This de facto “geoarchaeological” approach remained rather self-contained throughout the successive developments and involutions of archaeological methodologies and theories. This owes mainly to the low “signal to noise ratio” of Paleolithic contexts, where the anthropic signal is diluted

within a preponderant set of processes and features of natural origin, and where researchers face long timescales and a succession of different paleoenvironments.

The excavation of coastal shell middens containing ancient artifacts in southern Scandinavia since 1848, carried out by archaeologist J. J. Worsaae, paleontologist J. Steenstrup, and geologist J. G. Forchhammer, is seen as the first episode in interdisciplinary archaeology. Such excavations led to the understanding that the middens were not natural formations but in fact the remains of human occupation, and permitted also the refinement of Thomsen’s “three-age system.” Slightly afterwards, the discovery of pile dwellings in Switzerland, due to an exceptional lowstand of lake levels in 1853, promoted the collaboration between archaeologists and natural scientists. Not just geologists, but also plant specialists begun to be involved from this point on, as waterlogged conditions allowed for the perfect preservation of wood and botanical remains (i.e., pollen, fruits, seeds). The discovery of Swiss pile dwellings promoted the collaboration between earth scientists and archaeologists also in Italy as early as 1861, a circumstance overlooked in most accounts of the birth of interdisciplinary archaeology. The work of geologist B. Gastaldi, naturalist B. Strobel, and archaeologist L. Pigorini on pile dwellings and Bronze Age settlements in north Italy (and before them of geologists G. Scarabelli and F. Stoppani) is remarkable.

Differently from “architectural” or “antiquarian archaeology,” this new “scientific archaeology” (Trigger 1989; see *ARCHAEOLOGY*) faced the *necessity* of resorting to geology and natural sciences. The archaeological objects and behaviors scholars sought were in fact deeply entangled in natural deposits, processes, and features. In this framework, the role of geology-derived *stratigraphy* was again crucial. It permitted objects to be ascribed to layers (thus enabling seriation after Thomsen’s system), to carefully record the sequences being excavated, to correlate sites and, most importantly, it constituted a communal reference point for the different specialists to interact.

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

© 2018 John Wiley & Sons, Inc. Published 2018 by John Wiley & Sons, Inc.

DOI: 10.1002/9781119188230.saseas0255

“Scientific archaeology” has therefore shared a set of concepts with geology since its very early development. Amid these concepts a key role is played by the laws of stratigraphy, formulated by N. Steno and J. Hutton in the 1600s and 1700s respectively, which, together with uniformitarianism, constitute two of the building blocks of modern geology. Based on this, the search for a definition of what geoarchaeology is can be avoided, stating more simply that geoarchaeology *is*, in fact, just archaeology. Geological principles have been at the very core of “scientific” or “modern” (or, at the very least, “stratigraphic”) archaeology’s development as opposed to other external scientific disciplines whose methods developed independently from archaeology and were then applied to it as “ancillary techniques.”

A matter of scales

Quoting the words of K. W. Butzer, who first crystallized the term “geoarchaeology” in 1973 (Hill and Rapp 2010; Hill 2017), “it [...] serves no practical purpose to seek logical, unifying structures or categories for what geoarchaeologists do” (Butzer 2008, 403). The fact is that, owing to the strong bonds that connect earth sciences and scientific archaeology since its very beginning (see before), geoarchaeologists deal with a wide plethora of aspects that are relevant to archaeological research. Yet, a characteristic common to all such aspects is the multiscale approach of geoarchaeology (see Goldberg and Macphail 2006; Butzer 2008). Surveying the distribution of a series of sites across a whole region or interpreting a X-ray diffractogram obtained from a few sand grains should be viewed as a movement along a continuum of information, from a broad to a very detailed level of observation. Such a continuum begins with the knowledge of the wider geological and geomorphological context in which a site or a study area is set, indicatively at scales of 1:100,000, 1:250,000 or even smaller. This is also referred to as the “macro-scale” (Butzer 2008). Information at this scale is normally obtained through the study of cartography (geological, geomorphological, topographic, soil, ancient maps) and remotely sensed data (aerial photos, satellite imagery, DEM,

LiDAR, processed images, etc.; see AIRBORNE REMOTE SENSING), when these are available, or by geological survey when preexisting data are unavailable or inaccessible. Without a clear cut between the macro-scale and the meso-scale discussed below, geoarchaeology is often concerned with the use of archaeological sites, artifacts, or geogenic materials (e.g., tephra; see TEPHRA AND VOLCANIC ASH ANALYSIS) to date geological events, and, conversely with the evaluations of their impact on past human groups or societies or their effects on site preservation. Such geological events can be volcanic eruptions, river avulsion, aggradation and downcutting, intervals of stability with soil formation, and so forth. The list also includes the impact that seismic activity and other structure-related processes (e.g., subsidence and consequent submergence of coastal sites, tsunami inundations, uplift along faults) had on past societies. These constitute the focus of archaeoseismology (see ARCHAEOSEISMOLOGY). Activity of faults is also of interest to geoarchaeologists facing the study of very long timespans, where dislocation of layers and significant alteration of the original topography might have taken place (e.g., Olduvai Gorge, Tanzania).

Paleoenvironmental reconstruction (see PALEOENVIRONMENTAL RECONSTRUCTION), one of the main fields of application of geoarchaeology, encompasses the analysis of litho- and biostratigraphic sequences and makes large use of absolute dating methods. Paleoenvironmental reconstruction might be based upon many very specific, local, or site-scale observations, but normally produces a regional or supraregional picture, comprising for example, climate changes, sea level variations, glaciers advance or retreat, evolution of estuarine environments or shorelines, desert areas dynamics. These past environmental or paleogeographical changes are relevant for archaeology as they are evaluated in terms of population dynamics and human adaptive responses.

Lastly, as geological maps represent the distribution and age of lithotypes in a given area, they are used for studies of provenance and sourcing of rock materials used for artifacts (chert, obsidian, flint clay, volcanic lithics, etc.) or for construction. Provenance and sourcing are determined by comparison of artifacts’ composition

with the lithotypes present in the area, by means of methods such as thin section petrography and X-ray techniques, among others. The geological composition of an area also influences the composition of the sediments that formed upon weathering and were eventually eroded and redeposited. The information on local sediments' composition is used in pottery studies (see *ELEMENTAL ANALYSIS OF POTTERY*) aimed at ascertaining the sourcing of mineral temper or of clays, or at identifying the origin of pottery (i.e., locally produced vs. allochthonous or imported ware).

Advancing towards a more detailed level of observation along the continuum of scales, the geomorphic unit(s) of interest, such as "floodplain," "dune system," "alluvial terrace," and so on should be defined. This more immediate background to the site or study area greatly influences the sedimentary dynamics that can predate human occupation (hence forming the "natural substrate" to it), interact with it (causing intermittent or discrete occupations) or postdate it (burial conditions). Of crucial importance is the distinction between areas of active and areas of inactive sedimentation. A site set on a geomorphic unit where sedimentation is inactive, as for example a relict alluvial terrace, will be subject to soil formation, with processes such as bioturbation and oxidation homogenizing and altering the archaeological deposits. Here, moreover, the stratigraphic sequences will be condensed, that is, there will be no sediments or soils formed thereon separating successive occupation episodes. Erosion, agricultural impact, and construction work will have a more severe impact on shallowly buried or, worse, surficial deposits. On the other hand, the stratigraphic sequence of sites located in areas with active sedimentation, such as a floodplain, will suffer less from soil mixing and consist of discrete occupations. Deeper burial might also result in the avoidance of later anthropic impacts, and the presence of a groundwater table could favor preservation of organics. Nevertheless, active sedimentation might imply strong erosion and total loss of archaeological deposits. Cores or hand auger observations in the near-site can augment the information at the meso-scale providing quick access to the buried record. Sedimentation and erosion can be triggered by

supraregional factors such as climate change or tectonics, but human impact on the environment often plays a role. This is the case for example, when vegetation clearance and agricultural practices along slopes results in the erosion of topsoil and in the deposition of colluvium (see French 2003). The concepts and analytical methods of pedology, the science studying soils, are often applied when reconstructing ancient land use. The latter encompasses practices such as deforestation (e.g., uprooting of trees and slash-and-burn), secondary clearance, manuring and soil amelioration, irrigation, tillage, terracing, and so on. These all alter profoundly the original environment around a site and leave traces in the soil-sedimentary record. Pedology can be also used to perform land evaluation, the determination of the suitability of ancient soils for specific land utilization types, such as the growth of certain crops or their use as pasture. The potential of pedology in geoarchaeology relies also on the fact that soil properties can change over very short distances, thus varying at a scale similar to the meso- or site-scale (see below). Soils form in response to a series of "soil forming factors," namely climate, organisms (including humans), relief, parent material, and time (known as "Jenny's equation"—quoted also in Hill and Rapp 2010, 3009). As these factors are recorded in soils, their role in the reconstruction of environmental and anthropic dynamics in a site and in its surroundings is paramount.

At the end of the continuum, the geoarchaeologist works at the site or "intra-site" scale. Here the focus can be on a group of stratigraphic units (with or without intercalated soils), on a single unit or soil horizon, on a specific anthropic feature (a fireplace, a pit, a floor, etc.), or natural characteristic (a mottle, a nodule, a biogallery) or on a single eco- or artifact. On site, the geoarchaeologist might be asked to discriminate between units of natural versus anthropic origin, to do correlations within the site and outside of it in the surrounding landscape, to collect samples for detailed stratigraphic studies (e.g., by means of soil micromorphology; see *MICROMORPHOLOGY*) or for other specialists. By working on site during the excavation, the geoarchaeologist will be able to choose the analytical techniques and to design a sampling strategy aimed at answering appropriate and relevant

archaeological questions. The greatest possible integration between different disciplines will be facilitated by knowledge of the stratigraphy of the site. Besides sampling, a great deal of work consists in describing lithostratigraphic units or soil horizons. Descriptions normally make use of a standard terminology, agreed upon at the national or international level, thus facilitating the presentation of data and communication with other specialists. Standard descriptive terminologies in sedimentology or pedology obviate archaeology's lack of specific stratigraphic nomenclature (notwithstanding the efforts of some authors in the 1980s and 1990s to create one).

One of the main tasks of the geoarchaeologist working at the site-scale is to reconstruct site formation processes, sometimes referred to as "formation processes of the archaeological record" (Schiffer 1987). In Schiffer's view formation processes are the link between the behaviors (what archaeologists aim at reconstructing) and the deposit (what archaeologists excavate). This basically means that deciphering formation processes implies disentangling all the processes, human (or behavioral or cultural) and natural, whose interactions shaped the deposit, that is, the artifacts, the biofacts, and the sedimentary matrix around them. Particular attention is given to "post-depositional processes," and "taphonomy" (see TAPHONOMY)—a term derived from paleontology indicating "the inputs, processes, and filters that transform a living community to a death assemblage and ultimately a fossil palimpsest" (definition by Butzer 2008, 404)—is often used. Site formation studies often benefit of the high resolution of the micromorphological study of thin sections, which allows observing artifacts and biofacts together with the sediments encasing them as they occur in the deposit (see Nicosia and Stoops 2017). In this approach the undisturbed sedimentary matrix provides the fundamental "context" to biofacts and artifacts (Goldberg and Berna 2010).

It is at the site-scale that probably the approaches of the geoarchaeologist and of a standard geologist differ the most. Here, in fact, one has to face the fact that the stratigraphic sequence of an archaeological site "largely reflects the historical and social particularities of the people who created it" (Lucas 2012, 89). Moreover, the site-scale is peculiar to archaeological contexts,

where relevant variations in color or texture can happen in a few centimeters, a circumstance which makes archaeological field stratigraphy in itself a form of "micro-stratigraphy" when compared to the scale of geological stratigraphy.

Perspectives

If really "geoarchaeology is archaeology," why then do many excavations still lack any geoarchaeological component and why, compared to the amount of archaeologists, are geoarchaeologists so few? One possible answer is that archaeologists receive little, if any, courses in disciplines of geosciences relevant to archaeology (e.g., geomorphology, sedimentology, pedology, etc.—see Goldberg and Macphail 2006; Goldberg 2008). This is rather absurd if we consider that exactly because *stratigraphy* is at the very core of scientific archaeology, a large part of what archaeologists do during excavation is observing, labeling, grouping, and correlating volumes of sediments or soil, ultimately producing a stratigraphic sequence. Conversely, also geologists receive little or no training in archaeology at university. Often times they encounter difficulties in understanding the scale and the subtleties of archaeological features and the type of information relevant for archaeological research. The geoarchaeologist should be able to bridge between different scales, and should be actively involved in the field during excavation. This would allow formulating relevant questions and appropriate lines of research. By this active participation, proper sampling strategies—with stratigraphy as the central point around which all specialists and specialisms revolve—could also arise.

High Performance Liquid Chromatography (HPLC)

KATARZYNA LECH

Warsaw University of Technology, Poland

Introduction

High performance liquid chromatography (HPLC) is a kind of column chromatography conducted under high operating pressures that is used to separate the compounds in a liquid mixture.

The concept of chromatography was born in the early twentieth century when a Russian botanist, Mikhail Tswett, separated a mixture of plant pigments in a column. He presented his work in 1903 at the meeting of the Warsaw Society of Natural Sciences, and the term “chromatography” was introduced three years later in his publication. HPLC was developed only in the 1970s–80s together with new instrumentation and columns filled with small particles. These solutions led to superior resolving power, an increase in specificity, precision, and accuracy, as well as a reduction in the sample amount and analysis time.

Nowadays, modern HPLC is supported by a wide range of detectors, which provide information about the complexity, identity, and quantity of the components in a mixture using the physicochemical properties of the analytes. Furthermore, the successful coupling of HPLC with mass spectrometry (MS) (see MASS SPECTROMETRY (MS)) offers the perfect analytical tool that combines the excellent separation capability of HPLC with the unsurpassed sensitivity and specificity of MS. All this makes HPLC one of the most important separation techniques that, unlike gas chromatography (GC), is not limited by analyte molecular mass, volatility, or thermal stability; thus HPLC can be used to separate solutes over a wide polarity range, from small organic molecules and ions to large biomolecules and polymers.

Concept

HPLC separation requires two phases: the stationary phase, which is the solid media packed into a column; and the mobile phase (eluent), which is a liquid forced through the column under high pressure. A bed of the stationary phase is formed by fine, totally porous or pellicular particles (a solid core with a thin porous outer shell) of 5 μm diameter or less with a narrow size distribution. Their surface can be modified by either physical or chemical means, which is the starting point for various chromatographic modes. The mobile phase is usually a mixture of two or more solvents, water, aqueous buffer solutions, and/or miscible organic solvents, which is capable of dissolving the analytes. Differential migration of sample components through the column depends on the equilibrium distribution of each compound between the mobile and stationary phases. The equilibrium distribution is continuously disturbed by flows of the fresh mobile phase, and re-established immediately by mass transfer from one phase to another. Consequently, the solutes move along the column, and the movement is determined by the composition of the mobile phase, the composition of the stationary phase, and the separation temperature.

Basic HPLC systems consist of a pump (with a mixing chamber), injector (manual or automatic), column (the heart of the chromatograph), and detector that are connected together via tubing with a narrow inner diameter (to minimize band broadening), as well as a data collection device that visualizes a detector signal in the form of a chromatogram.

The peaks of various sizes rising from a baseline of the chromatogram provide information about each component of the sample. The retention is a measure of the velocity at which a solute moves in a chromatographic system. The position of a peak in a chromatogram is characterized by its *retention time* (t_R), which is defined as the time elapsed between the injection and the appearance of the peak maximum (Figure 1). The retention time consists of two components: the

Figure 1 Chromatographic parameters.

time that the solute spends in the mobile phase, and the time it spends in the stationary phase. The first component corresponds to the time taken by an unretained compound, (i.e. a solute that does not interact with the stationary phase at all), which is called the *column hold-up time* (t_0), while the second component is the difference between retention and hold-up time, known as the *adjusted retention time* (t'_R).

The identification of analyte is based on the comparison of the retention parameters of an unknown with those of reference materials determined under identical experimental conditions. Although retention is a property of a solute, it is not a unique property. Therefore identification often requires comparison of other qualitative information based on physicochemical properties of an analyte, such as molecular mass, characteristic absorption or re-emission of electromagnetic radiation that can be provided by the detector. The linear relationship between detector response (peak area or height) and the concentration of the analyte is used to determine the amount of each analyte in the sample.

The column should have the capacity to retain the solutes, and it should be selective to resolve them. The chromatogram of well-separated compounds should present peaks located as close to each other as possible, but not overlapping. The degree of separation between two peaks is expressed as the *resolution* (R), which describes

the relationship between distance of the peaks and their average *widths* at the bases (w) obtained by extrapolating the relatively straight sides of the peaks to the baseline, or at their half height ($w_{0.5}$) (see Figure 1).

$$R = 2(t_B - t_A) / (w_A + w_B) \\ = 1.18(t_B - t_A) / (w_{A,0.5} + w_{B,0.5})$$

The goal of HPLC separation is to provide the optimal resolution at minimum time. If individual values of the resolution are 1 or greater, the separation is complete, but it does not mean that the baseline between the peaks is reached. The valley is of about 94 percent for two peaks of similar height. Entire separation is only obtained if the resolution is 1.5, and it needs to be higher in the case of a greater height ratio between the peaks.

The resolution can be improved by increasing the *selectivity* (α), *average capacity factor* (k'_{av}), and *number of theoretical plates* (N) that characterize the column efficiency. k'_{av} is dependent mainly on the packing material, but it can be varied by modifying the composition and strength of the mobile phase. Also α is a function of the porous media in a column, but it can be altered by changing some of the eluent parameters as well (the constituents, strength, temperature, and pH). Peak broadening, and hence efficiency, depends on the column itself (the dimensions, particle size, and quality of the column packing) as well as on the mobile phase flow rate.

Table 1 Characterization of HPLC modes.

<i>HPLC mode</i>	<i>Stationary phase</i>	<i>Mobile phase</i>	<i>Analytes</i>
Normal-phase liquid chromatography (NPLC)	Silica, alumina, polar bonded phases	Nonpolar solvent mixed with slightly more polar solvent	Polar solutes readily soluble in organic solvents
Hydrophilic interaction liquid chromatography (HILIC)	Silica, polar bonded phases	Aprotic solvent (miscible with water) with a small amount of water	Highly polar compounds or with limited solubility in water
Reversed-phase liquid chromatography (RPLC)	Hydrophobic bonded phases	Water or aqueous buffers (alternatively with ion-pairing reagent) mixed with polar organic solvent miscible with water	Solutes with wide range of polarity
Ion-exchange chromatography (IEC)	Anion and cation exchange resins	Aqueous solutions of salt, often mixed with small percentage of organic solvent	Mainly small inorganic and organic ions
Size-exclusion chromatography (SEC)	Highly porous substrate	Aqueous buffers or organic solvents capable of dissolving analytes	Biomacromolecules, polymers
Affinity chromatography	Matrix with bonded biochemicals (affinity ligands)	Aqueous buffers with appropriate pH and ionic strength	Proteins, nucleic acids

Strategies

HPLC elution of solutes from the column can be carried out with two operating methods. Isocratic elution consists of keeping a constant composition for the mobile phase during the analysis. It is suitable for the solutes of similar affinities for the stationary phase. However, many complex samples contain components that differ widely in retention. In that case the peak width of strongly retained solutes increases with increasing retention time, causing difficulties in their detection. The resolution can be improved using a gradient elution technique that assumes changes in the eluting strength of a mobile phase, and hence in its composition, during the chromatographic process. This is achieved by employing two to four different solvents or their solutions. As a consequence, it is possible to separate both weakly and strongly retained solutes while achieving appropriately short elution times for the later peaks.

The particular combinations of stationary and mobile phases are the bases for a wide variety of separation modes (Table 1), such as normal-phase, reversed-phase, hydrophilic interaction, ion-exchange, size-exclusion, and affinity chromatography.

Reversed-phase liquid chromatography (RPLC) is the most widespread separation mode in modern HPLC that uses a nonpolar stationary phase and a polar mobile phase. The most widely used stationary phase is silica modified with a C18 group, but phases with bonded C8, phenyl, pentafluorophenyl, or cyano groups are also applied. Typical mobile phases consist of water or aqueous buffers mixed with polar organic modifiers miscible with water, such as methanol, tetrahydrofuran, and acetonitrile. Differences in the selective interactions of these organic solvents (strong acidic hydrogen bonding of methanol, strong basic hydrogen bonding of tetrahydrofuran, and strong dipole interactions of acetonitrile) cause the differences in solubility of their mobile

phases. Moreover, the use of ionic additives (i.e., buffers, neutral salts, weak acids, ion-pairing reagents) allows exploitation of secondary chemical equilibria, such as ion suppression, ion-pair formation, or metal complexation, to change the selectivity of the separation process. Consequently reversed-phase liquid chromatography is applicable to simultaneous separation of a very wide range of nonpolar and polar solutes, including ionic, acidic, or basic analytes, homologous or oligomeric series with different numbers of nonpolar or weakly polar groups or moieties. The solutes are generally eluted in order of decreasing hydrophobicity, wherein if the gradient elution is used, the retention decreases with the increase of organic modifier content in the mobile phase equivalent to the decrease of the polarity of the mobile phase.

Conventional HPLC allows for a satisfactory analysis time, band broadening, and efficiency at pressures limited to 400 bar. However, the use of smaller core-shell particles (less than 2.5 μm) and thus shortening of the diffusion path can improve these parameters. Due to the exceptionally high working pressures up to 1200 bar and rapid mass transfer at high flow rates of the mobile phase, ultra-high performance liquid chromatography (UPLC or UHPLC) is capable of analyzing solutes with even greater speed, resolution, and sensitivity.

Detection

The detector constitutes an integral part of the HPLC system that monitors changes in some physicochemical properties of the column effluent and converts them into an electrical signal. There are various types of detectors, such as optical (see OPTICAL SPECTROSCOPIES), electrochemical, or spectrometric detectors, but the UV-Vis (spectrophotometric) detector is the most commonly used in RPLC because of its wide linear range, relative sensitivity, applicability to gradient elution, low cost, and ease of use.

Spectrophotometry belongs to the spectroscopic techniques based on the characteristic absorption of ultraviolet and/or visible radiation by compounds containing chromophores (parts of molecules, mostly multiple bonds, such as

$\text{C}=\text{C}$, $\text{C}=\text{O}$, or $\text{C}=\text{N}$, that can be excited). Since dienes absorb around 215 nm wavelength radiation and higher, aromatics around 254 nm, phenols roughly 260–280 nm, and the other chromophores causes further shifts to longer wavelengths (bathochromic effect), the UV-Vis detector is useful in detecting most organic compounds.

Two types of absorption detector are particularly popular: the variable-wavelength detector (VWD), which is capable of monitoring only a single detection wavelength at a time, and the diode-array detector (DAD), which is able to record chromatograms at multiple wavelengths simultaneously, whereas polychromatic light passing through the sample can provide also the full spectrum of each peak.

The next detector uses fluorescence emission, which makes it much more sensitive and compound-selective than a UV detector. However, it is much less commonly used, since most compounds do not have useful native-fluorescing properties. Consequently, derivatization of the analytes is obligatory to detect them.

The use of mass spectrometry (MS) (see MASS SPECTROMETRY (MS)) as a HPLC-detection technique has recently become more widespread. Such a hyphenation combines the advantages of both analytical techniques, providing a more powerful tool for identification and quantitation. The MS offers very low detection limits, excellent separation capability, and high selectivity that increases either with the MS resolution or with the use of fragmentation. Tandem mass spectrometry (MS/MS) either provides structural information about the analyte or allows better selectivity and sensitivity for quantitative analysis, based on analyte fragmentation. In consequence, HPLC-MS/MS in the multiple reaction monitoring mode (MRM) is extremely powerful for target-compound analysis.

Since the MS can only detect charged species, the critical point of this system is the interface that is able to generate ions directly from solution and transfer them into the gas phase. This is possible thanks to atmospheric-pressure ionization techniques, such as electrospray ionization (ESI), atmospheric-pressure chemical ionization (APCI), and atmospheric-pressure photo ionization (APPI). Their applicability depends on the polarity and size of the analytes, hence ESI

is the most common interface combined with RPLC. The basic compounds ionized by ESI are mostly protonated, and thus positively charged $[M + nH]^{n+}$, while the acidic compounds are deprotonated forming negative ions $[M - nH]^{n-}$ (in most cases $n = 1$). Ionization can be aided by the use of pH control buffers commonly used in RPLC, but only volatile ones (i.e., ammonium bicarbonate, ammonium formate, formic acid) that are also compatible with an ESI MS system.

HPLC in archaeology

Archaeological objects are unique research materials: not only extremely complex (they contain original components, degradation products, and various contaminants), but also valuable. Although HPLC requires sampling followed by extraction of the analytes, and in consequence by destruction of the examined pieces, it may deliver comprehensive information on the organic compounds isolated from the extremely small samples that cannot be obtained by any noninvasive or nondestructive technique. Thus research on archaeological objects can be classified as a typical trace analysis applied in forensic science.

Since natural dyes (see DYES) consist of a mixture of colorants, RPLC is the most widely used technique for their identification in textiles (see TEXTILES), paintings, varnishes, polychromies, and papers. Separation of the components is carried out mainly on a C18 stationary phase—universal and recommended for the analysis of natural products. The hydrophobicity of coloring compounds is very diverse and requires the use of a gradient elution, wherein the mobile phase is usually a mixture of water with methanol or acetonitrile with addition of pH modifiers (i.e., formic acid, trifluoroacetic acid, phosphoric acid, or phosphate buffer), but their choice depends to some extent on the detection technique. Other stationary phases, such as phenyl, C4, C8, and NH_2 , are much less frequently used, although some of them provide very good results. The amino column requires the use of an ion-pairing reagent, such as sodium dodecyl sulfate (SDS).

All colorants that are components of natural organic dyes can be effectively separated

by RPLC, even if some of them have very long retention, but not every kind of detection can be used to detect them all (Figure 2). Two detectors, UV-Vis and MS, are the most widely used in the identification of dyestuffs. In so far as the use of spectrophotometry is particularly reasonable for the study of colorants (due to the numerous chromophores, they strongly absorb radiation not only in the ultraviolet, but also in the visible range), mass spectrometry is not so universal in this case. Some nonpolar compounds, such as 6,6'-dibromoindigotin, crocetin, or bixin, are ionizable to a negligible extent, especially with ESI. However, since this group is not common, and the advantages of the ESI MS detector towards the other colorants are enormous, a coupling of both detection techniques is an increasingly common solution that provides a complete set of information about the sample.

HPLC-MS is applied to analyze triacylglycerols in archaeological residues (see FOOD RESIDUE ANALYSIS and ORGANIC RESIDUE ANALYSIS), and also lipid binders (see PIGMENTS AND BINDERS), as it provides more accurate results than typically-used GC-MS (see GAS CHROMATOGRAPHY-MASS SPECTROMETRY (GC-MS)). Separation is performed in the reverse phase mode using a C18 column with gradient elution (mainly methanol/isopropanol, or acetonitrile/dichloromethane). Detection can be carried out with both APCI MS and ESI MS, but it needs to be compatible with the eluent used. The achieved triacylglycerol profiles give the content of individual fatty acids, so providing the necessary information to determine the origin of fat in a sample.

Proteinaceous binders (see PIGMENTS AND BINDERS) in artistic paintings can be identified by HPLC with UV-VIS or fluorescence detection, but the analysis of hydrolyzed amino acids requires a pre-column derivatization. The best separation results on a C18 stationary phase are provided by phenylisothiocyanate, 4-dimethylaminoazobenzen-4'-sulphonyl chloride used with UV-Vis detection, as well as by 9-fluorenylmethyl chloroformate and 6-aminoquinolyl-*N*-hydroxysuccinimidyl carbamate combined with a fluorescence detector, whereas a solvent system is based on sodium acetate, triethylamine, water, and acetonitrile. However, there is also an alternative to the

Figure 2 HPLC chromatograms of extract from green fiber (from a fifteenth-century chasuble dyed with weld and woad) provided by an ESI MS/MS detector in (a) the negative and (b) the positive ion mode, and by UV-Vis detector at (c) 280 nm and (d) 550 nm.

derivatization. The first approach is to apply ion-pairing reagents together with less popular but specific detectors, such as a chemiluminescent nitrogen detector. The second concerns the use of HILIC coupled with ESI MS/MS.

The identification of natural dyes, binders, or food residues is based mainly on a fingerprint approach that compares a complex set of peaks with those achieved for the reference samples. However, if the characteristic chromatographic profile or markers do not exist, the identification approach may involve multivariate analysis (see MULTIVARIATE ANALYSIS) methods, such as principal component analysis (see PRINCIPAL COMPONENT ANALYSIS) (PCA) and partial-least squares discriminant analysis (PLS-DA), where chromatographic data constitute the basis of further analysis and identification.

HPLC used for chromatographic purification and isolation of collagen peptides significantly improves ¹⁴C bone dating (see DATING IN ARCHAEOLOGY).

Infrared Absorption Spectroscopy (IR, FTIR, DRIFT, ATR)

MICHAEL B. TOFFOLO

Université Bordeaux Montaigne, France

FRANCESCO BERNA

Simon Fraser University, Canada

Infrared (IR) absorption spectroscopy is the study of the interaction of infrared radiation with matter. When irradiated, functional groups (clusters of atoms or bonds within molecules, e.g. $[\text{CO}_3]^{2-}$) in solid, liquid, and gaseous materials vibrate or rotate in specific modes that depend on the nature of atoms, interatomic chemical bonds and dynamic group properties. Each vibration mode corresponds to the absorption of a particular frequency in the infrared region ($14,000\text{--}20\text{ cm}^{-1}$), which results in a spectrum characteristic of a specific functional group (Diem 2015). Therefore, IR absorption spectroscopy can be used to identify different compounds in organic and inorganic substances, including materials of archaeological importance (Artioli 2010).

Infrared radiation was discovered in 1800 by Sir William Herschel, but its application to materials science did not expand until the 1930s, when the first commercial IR spectrometers were developed for the synthetic rubber industry. These instruments included an infrared radiation source, a sample chamber, a monochromator based on an optical grating or prism, and a detection system (Derrick, Stulik, and Landry 1999). A major technological breakthrough was the replacement of the monochromator with a Michelson interferometer in the 1960s. This device produces an interferogram that is converted into an infrared spectrum using the Fourier transform, thus improving the resolution of measurements and reducing noise and detection limits. This method, called Fourier transform infrared spectroscopy (FTIR), quickly

became the standard in IR studies. By the 1970s, FTIR spectrometers were combined with a dedicated computer, which dramatically increased the rapidity of measurements (Derrick et al. 1999).

FTIR measurements are mostly performed in transmission mode by calculating the absorbed component of the incident beam as a function of frequency. The beam passes through a few tens of micrograms of powdered sample suspended in a potassium bromide (KBr) pellet or dispersed in an oil film in between potassium chloride (KCl) windows. Both mediums do not absorb IR radiation. The non-absorbed component of the incident beam is collected by a detector. The frequency absorptions of the functional groups in the sample are obtained against a background of air to subtract the contributions from water vapor and carbon dioxide (CO_2). Sample preparation and measurement typically take less than five minutes. The identification of the different phases that appear in the infrared spectrum is done by comparison with reference spectra of standard materials (e.g., Chukanov 2014; the online library of the Kimmel Center for Archaeological Science, <http://www.weizmann.ac.il/kimmel-arch/infrared-spectra-library>). As the intensity of the IR absorptions has a precision ranging between 10–20%, FTIR spectroscopy is a method preferentially used to determine the presence of different chemical phases above the detection limit. Semi-quantification can be achieved by preparing standard mixtures for calibration. If the sample is crystalline, X-ray diffraction is preferred for quantification.

Another important acquisition mode of IR spectra is based on the reflection of the incident beam. In diffuse reflectance Fourier transform spectroscopy (DRIFT), about 2 mg of powdered sample mixed with KBr is placed in a cup-holder and leveled off to obtain a flat surface, which is then irradiated with infrared light. The beam penetrates the surface by a few micrometers and is partially absorbed and reflected by the functional groups in the sample. The diffusely reflected component of the beam is finally directed to a detector. The background spectrum is collected on a pure KBr powder. In attenuated total

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

© 2018 John Wiley & Sons, Inc. Published 2018 by John Wiley & Sons, Inc.

DOI: 10.1002/9781119188230.saseas0325

reflectance (ATR), the incident IR beam passes through a crystal of high refractive index (e.g., diamond, silicon, germanium, or zinc selenide) that is in contact with the surface of a powdered sample. The beam reflects within the inner surface of the crystal and generates an evanescent wave that penetrates into the sample by a few micrometers. The reflected component is then collected by a detector. The background spectrum is generally collected on air. DRIFT and ATR devices usually consist of sample chambers that can be conveniently attached to a regular FTIR spectrometer by replacing the transmission chamber.

Transmission and reflectance measurements can be performed also on extremely small samples by combining a spectrometer with an optical microscope, where the nosepiece includes optical objectives and IR condensers. Reflectance measurements are generally carried out in total reflectance mode, where the beam does not penetrate the surface, or in ATR mode following the procedure described above. In total reflectance, the background spectrum is collected on a gold plate. The IR microscope setup is particularly useful in the characterization of minute particles (approximately 50–300 μm), and thus it is suitable for the structural analysis of valuable works of art, as well as in forensic investigation (Derrick et al. 1999). FTIR microscopy can also be used in the analysis of archaeological sediments in thin-section (e.g., Berna et al. 2012). Therefore, it is possible to integrate chemical, mineralogical and spatial information regarding the different components that occur in sediments. The use of automated stages allows chemical mapping of relatively large areas.

Due to the small sample size required for analysis, FTIR spectroscopy has been applied to archaeological materials since the 1950s, and significantly contributed to the development of the fields of archaeometry and conservation science. More specifically, FTIR spectrometry has proved useful in the characterization of materials such as amber, parchment, textile, bone, mollusk shell, plaster and mortar, faience, varnishes, dyes, pigments, and organic compounds used in paintings (Derrick et al. 1999; Artioli 2010). For instance, DRIFT analysis has been successfully employed in the provenancing of amber artifacts by matching their infrared spectra with the spectra of geological samples from a reference database (Angelini

and Bellintani 2005). In addition, FTIR spectrometry is routinely used as a screening method to check the purity of charcoal, collagen, and cellulose for radiocarbon dating (Weiner 2010).

With the advent of portable spectrometers in the 1980s, FTIR spectroscopy became a rapid and convenient method for on-site analysis at archaeological excavations (Weiner and Goldberg 1990). This approach to fieldwork presents major advantages, including the possibility of obtaining real-time information regarding the archaeological record that can be used to modify the excavation strategy as needed, and the ability to trace the boundaries of features that are invisible to the naked eye. In addition, samples are collected only from specific archaeological contexts relevant to the research questions at stake and immediately analyzed, instead of blind-sampling the entire site for post-excavation laboratory work (Weiner 2010).

Since FTIR spectroscopy is sensitive to the molecular bond interaction level, this method is especially suited for the identification of both crystalline and amorphous/disordered inorganic materials, as well as organic materials. Disordered and organic materials are particularly common in sediments at archaeological sites, and include opaline phytoliths, bone collagen, charcoal, lignin, cellulose, and humic acids. Using FTIR spectroscopy it is also possible to assess the degree of atomic order of crystalline phases exposed to fire, which changes their interatomic chemical bonds, and thus identify pyrogenic calcite, heat-altered clay minerals, and burnt bone (Berna et al. 2007; Regev et al. 2010; Weiner 2010). Another important aspect is the state of preservation of the archaeological record, which depends on the nature of the sedimentary matrix and on environmental conditions at a specific site. Diagenesis may alter the chemical properties of sediments and artifacts and thus lead to misleading interpretations of formation processes and human occupation. FTIR spectroscopy can track the formation of authigenic diagenetic minerals such as phosphates, nitrates, and sulfates, which form under specific environmental settings (Karkanas et al. 2000). In general, the results of FTIR analysis are best interpreted when integrated with the information obtained through other methods that address

the microscopic record, such as micromorphology (see MICROMORPHOLOGY) of sediments, phytolith analysis (see PHYTOLITH ANALYSIS), X-ray fluorescence (see X-RAY FLUORESCENCE SPECTROMETRY (XRF)), X-ray diffraction, Raman spectroscopy (see RAMAN SPECTROSCOPY), and more. This approach allows a better understanding of the archaeological record as a whole (see also MICROARCHAEOLOGY).

FTIR spectrometry is therefore a valuable method for the chemical characterization of archaeological artifacts and sediments, and can significantly contribute to addressing problems related to the preservation of the archaeological record, site formation processes, post-depositional alterations, stratigraphic correlations, absolute chronology, pyrotechnology, and more in general to past human activities. Currently, FTIR spectroscopy is being used to explore in more detail the different degrees of atomic disorder of mineral species altered or produced by fire and diagenesis, such as calcite (plaster and mortars), aragonite (wood ash), quartz (stone tools), clay minerals (combustion features), carbonate hydroxylapatite (bone and enamel), and other phosphates (authigenic). This requires the characterization of small samples within their original depositional context or structural configuration, and thus FTIR microscopy on thin-sections is a preferred method of analysis (Berna 2017). However, the large amount of point data collected from a thin-section poses the question of imaging and mapping of extensive surfaces into sizeable output, and the need for dedicated statistical means of interpretation of large datasets of infrared spectra. It can be predicted that in the near future the mapping of relatively large surfaces will be routinely applied to works of art that cannot be altered with sampling, such as paintings and frescoes, by using portable reflectance devices that operate in the near- and mid-IR spectral range (14,000–400 cm⁻¹). This approach will be extended also to standing sections of sediment at archaeological sites.

Ion Beam Analysis (PIXE/RBS)

ALESSANDRO LO GIUDICE and
ALESSANDRO RE

University of Torino and INFN, Italy

Ion beam analysis (IBA) methods can provide information on chemical composition and elemental distribution in a material. The strengths of IBA relative to other compositional techniques are the operation in air in a non-invasive way, analyzing objects of any shape and dimension, obtaining spatially resolved information (both surface mapping and depth profiling), with multi-elemental and quantitative analysis at very low concentrations (parts per million). Drawbacks of IBA are the non-portability, the impossibility of analyzing samples that are radiation or heat-sensitive, and the fact that the probing depth is limited to the superficial layers (maximum 200 microns). Moreover, since a small particle accelerator is required to generate the probing beam, the availability of IBA is limited to a small number of laboratories.

IBA is employed in the archaeological field to answer questions and solve problems that cannot be addressed using other analytical techniques, allowing the identification of materials, provenance studies, and evaluation of fabrication techniques and state of conservation. Its importance has increased over time thanks to the continuous technological improvements that have extended the number, shape, dimensions, and complexity of samples that can be analyzed.

IBA techniques require a particle beam (usually protons or alpha particles) with energies of a few mega-electronvolts impinging on the sample to be analyzed. Even though the first design of accelerator used for IBA dates back to the 1930s, complete applicability of the technique to the field of archaeology was reached only in the 1970s, when the first beam operating in air (and not in

a vacuum, as previously) was developed. In the 1980s another advancement was the adoption of focused ion beams down to a micron level, which increased the spatial resolution capabilities of IBA techniques and enabled mapping of the distribution of elements. IBA techniques are still continuously improving their performance and analytical capabilities; a review of recent achievements and future challenges can be found in Zucchiatti and Redondo-Cubero (2014).

The interaction of the beam particles with the nuclei and electrons inside the sample gives rise to many signals that can be detected, giving different information useful for different IBA techniques; a full list of these techniques can be found in Jeynes et al. (2012). In the archaeological field the best-used IBA technique is PIXE (particle induced X-ray emission), where the X-rays characteristic of the atoms inside the sample are detected, allowing the identification of the elemental composition (usually for elements heavier than sodium). The physical principle of X-ray emission is the same as that exploited in SEM-EDS and XRF (see X-RAY FLUORESCENCE SPECTROMETRY (XRF)), although those use different probes (electrons and photons respectively). The advantage of PIXE with respect to EDS is the greater sensitivity, allowing simultaneous detection of main, minor and trace elements (thanks to the lower braking radiation (“bremsstrahlung”), the detection limits are usually around 1–10 ppm) and the possibility of analyzing samples of almost any shape, dimension and material, not requiring a vacuum and so without the space limitations of a chamber. Even if other techniques (e.g., ICP-MS (see ICP-MS AND MATERIAL ANALYSIS)) can detect elements present at lower concentrations, PIXE and XRF are the only ones that can work in a non-invasive mode. While XRF can be portable (see PORTABLE X-RAY FLUORESCENCE SPECTROMETRY (PXRF)), an aspect very appealing in the archaeological field, PIXE requires the samples to travel to the laboratory to be analyzed. But once there, PIXE can quantify the element contents (also ppm) by means of the acquisition of only one spectrum, while XRF needs different

runs of measurements acquired with different experimental conditions, to take into account phenomena such as diffraction. Another key advantage of PIXE is that it is often coupled with other IBA techniques, giving complementary information and providing a wider overview to answer archaeological questions.

By the end of the 1990s a portable PIXE instrument has been realized for applications in the field of heritage studies: it is based on an annular radioactive source that generates the probing alpha-particle beam. Despite the portability, which is a very important aspect for the analysis of archaeological materials, there are some limitations that have to be highlighted: it is not possible to obtain spatial information (nor the elemental distribution on the surface nor the depth profiling) or to combine it with other techniques. Moreover, there are some issues both in the production and the duration of the radioactive source and the radioprotection rules to be followed when moving this instrument outside the laboratory.

Another widely used IBA technique is RBS (Rutherford backscattering spectroscopy), similar to the SEM-BSE, but using an ion probe instead of an electron probe. It is based on the measurement of the number and energy of the beam particles backscattered by the sample at a high angle (typically from 150–170° with respect to the beam direction). It gives information on the composition of the material (elements heavier than the impinging particles, which are usually H or He) with a sensitivity that, for heavy atoms, reaches the ppm level. Moreover it is possible to obtain information on the depth profile distribution of different elements, in the most favorable cases with a resolution of a few tens of nanometers. It is best suited for the analysis of elements with medium and high weight in a light matrix and can give information up to around 10 µm depth. Due to absorption phenomena, RBS has some limitations when used in air or helium flux.

Other IBA techniques have been used in the archaeological field, usually coupled with one of the two main ones (PIXE and RBS) to give complementary information. Among them are:

- PIGE (particle induced gamma-ray emission), based on the detection of gamma-rays

emitted by a nucleus interacting with a particle and able to detect light elements (usually from lithium to sodium);

- IBIL (ion beam induced luminescence) or IL (ionoluminescence), similar to the cathodoluminescence used in electron microscopy, where the detection of UV-VIS-NIR photons emitted by the sample allows the identification of different phases, chemical zoning in minerals, or the presence of elements in very low concentrations (ppm) that are involved in luminescence centers (radiative recombination);
- NRA (nuclear reaction analysis), in which the products of nuclear reactions (usually protons or alpha particles) are detected, allowing the depth-profiling of some elements and the possibility of distinguishing among some isotopes;
- ERDA (elastic recoil detection analysis), where light atoms knocked out from the samples by heavy ions are detected (usually $Z < 15$, including hydrogen).

PIGE and IL can be used in air or helium flux, whereas NRA and ERDA give better results if employed in a vacuum on small samples, due to absorption effects.

In recent decades, a number of laboratories have developed one or more of the IBA methods and used them to analyze materials of interest in the archaeological field. A special mention is due to the AGLAE laboratory, which has operated in this sector at the Louvre Museum in Paris for almost 30 years; it is among the few IBA laboratories mainly devoted to the analysis of materials related to archaeology and heritage (Dran et al. 2004).

IBA techniques have been used to answer different archaeological questions and to analyze many different materials. The easiest questions IBA can answer is the identification of an unknown material through its chemical composition (metals, alloys, stones, gems (see GEMSTONES), glass (see GLASS AND FAIENCE), pottery (see ELEMENTAL ANALYSIS OF POTTERY), pigments (see CHARACTERIZATION OF PIGMENTS), bones (see BONES AND IVORY), etc.).

A more challenging question that IBA can often answer is the provenance of a material based on extensive compositional databases of

reference compounds. This topic is of particular interest for reconstructing old trade routes and exchanges, for which no written testimonies remain. Provenance studies usually require wide and long experiments, and the availability of many samples from known provenances that are employed to create a database. Some elemental markers have to be found, characterizing each provenance; usually trace elements or luminescence properties are very useful for this purpose, and binary graphs of two elements or multivariate analysis can help to group the results and highlight the differences among the provenances. After that, the unknown sample is measured and compared with the database to find which group of known sample it most resembles. This approach, often combining data from PIXE, PIGE, and IBIL, has already been used on different kinds of materials like glass (see GLASS AND FAIENCE), natural glasses (obsidians (see CHERT, SILEX, AND OBSIDIAN SOURCING)), stones (flint, lapis lazuli, jade, volcanic materials), gems (see GEMSTONES) (rubies, emeralds, garnets), pottery (see ELEMENTAL ANALYSIS OF POTTERY) (ceramics, porcelain), metals (gold, copper, iron), alloys (bronze), pigments (see CHARACTERIZATION OF PIGMENTS) and ivory (see BONES AND IVORY).

Using a similar approach, indirect dating (see DATING IN ARCHAEOLOGY) of an artifact can be obtained. If many samples produced in a known period are analyzed and create separated clusters on the basis of the concentrations of some chemical element (mainly trace elements), then, analyzing an unknown sample, it is possible to correlate it to the group of corresponding composition, and so to obtain an indirect dating for the sample. This method has already successfully been used for glasses (see GLASS AND FAIENCE) and pottery (see ELEMENTAL ANALYSIS OF POTTERY).

IBA also offers a unique tool to study other characteristics of archaeological materials, related to their fabrication techniques. For example, thanks to the combination of RBS and PIXE, a gilded object can easily be discriminated from a golden one, and the gilding thickness and composition can be evaluated. Another aspect related to metals is soldering (Demortier 1991); different techniques used by craftsmen can be distinguished, providing information about the technological level that a population reached in

different periods, and also about the presence of restorations (also made in antiquity).

The analysis of coins can provide useful information too: a debasement in the amount of noble metals can be correlated to periods of war or crisis, while the detection of trace elements can correlate different populations, suggesting exchanges among them. The study of differences between surface and bulk can also expose fakes or counterfeit coins, presenting a surface rich in the noble metal and a core where it is present in very low concentrations or absent (Beck et al. 2011).

Another aspect that IBA can help to clarify is related to the state of conservation (see CONSERVATION) of an archaeological object, and in particular about the presence and thickness of an alteration patina due to its burial or conservation conditions. In this case, the combination of RBS, PIXE and NRA, or the use of ERDA, can give the thickness and depth distribution of multiple alteration layers on metals, alloys, and glasses (see GLASS AND FAIENCE).

University of Oxford, UK; University of Gothenburg, Sweden

Introduction—elements, atoms, and isotopes

All naturally occurring materials are built of *elements*. Already in 1911 Ernest Rutherford had postulated that the large-angle scattering of positively charged α -particles that he observed could be produced only by an intense electric field, due to a positive charge, with most of the mass of the atom concentrated in the center, later named the *nucleus*. It was subsequently shown that elements consist of atoms built of a nucleus with a specific number of positively charged *protons*, and electrically neutral particles of similar weight known as *neutrons*. In its atomic shells the nucleus is surrounded by orbiting, negatively charged particles called *electrons* (Figure 1). The mass of electrons, by comparison with the protons and neutrons, is so small that it does not contribute significantly to the total mass of an atom. The positively charged protons and negatively charged electrons compensate the electrical charge of the atom; if the number of electrons is smaller or larger than the protons, the atom is electrically charged and then it is called an *ion*.

The number of protons in the nucleus is characteristic for each element and known as the *atomic number* (Z); this number is also equal to the number of electrons in the atom, which defines the chemistry of the atoms. The total mass of protons and neutrons defines the atomic mass of an element, called the *mass number* (A). In 1914 an English physicist, Joseph John Thomson, observed that the gas neon is composed of two types of atoms of atomic weights about 20 and 22. Several other scientists confirmed in the following years the hypothesis that the place occupied in the Periodic Table by a particular element must accommodate more than one kind of atom (Faure

1986, 4–5). These different atoms of the same element, having different masses, therefore different *mass numbers*, English chemist Frederick Soddy named for the first time in the years 1912–20 the *isotopes*, from the Greek for “same place” in the Periodic Table.

Each element is characterized by its *atomic number*, equal to the number of protons in its nucleus, while its isotopes are described by the *mass number*, which is equal to the sum of protons and neutrons in the nucleus of their atoms. The usual way of describing the atoms is writing the mass number on the upper left and sometimes the atomic number below, for example, the most abundant isotope of carbon is in the form $^{12}_6\text{C}$, where the number in the superscript, the atomic mass, is specific for the isotope of a given element. Since the symbol identifies the element specifically, the atomic number is most often omitted in the literature, as in the well-known isotope of carbon, ^{14}C .

The word *isotope* is sometimes used in parallel with the word *nuclide*, defined as a specific atom characterized by the components of its nucleus, in particular by the number of protons and neutrons in its nucleus.

Naturally occurring isotopes

Radioactive isotopes

Isotopes can be *stable* or *radioactive*, spontaneously mutating to another isotope with the emission of particles or gamma rays. The radioactive decay of a parent nuclide into a radiogenic daughter isotope (which may also be radioactive and decay further) is a process progressing at a constant rate specific for a given nuclide, called the half-life ($t_{1/2}$). The half-life is the time required for half of the given initial number of radionuclides to decay, according to the equation:

$$\frac{1}{2}N_0 = N_0 e^{-\lambda t_{1/2}}$$

where N_0 is the original number of nuclides, and λ is a physical constant.

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0335

Figure 1 Schematic representation of an atom, and nuclei of some light isotopes.

This process depends only on the nuclear structure of the nuclide and is independent of chemical and physical conditions such as temperature, pressure, humidity, and elemental compositions. The half-lives of various nuclides vary from microseconds to many millions of years. For example, ^{238}U has a half-life of 4.5×10^9 years, ^{14}C a half-life of 5.73×10^3 years, but ^{210}Pb only 22.6 years. In cases when a material contains radioactive nuclides, the measurement of their concentrations can be used for their dating.

Some radioactive isotopes can be used for identification of the elements and their quantity by measurement of the type and energy of their radiation (α , β particles, γ radiation), as for example in ^{14}C and U/Th dating as an alternative to mass spectrometry.

Other radioactive isotopes can be created artificially in nuclear reactors, for example, strontium, arsenic, copper, silver and gold have short-lived isotopes that are commonly used in neutron activation analysis (NAA) of chemical compositions of archaeological pottery, metals, and obsidian.

Stable isotopes

In the natural environment, there are three main sources of isotopes:

- *Primordial*: formed during elemental synthesis in supernova explosions.
- *Radiogenic*: the results of the radiogenic decay of other elements.
- *Cosmogenic*: produced by the interaction of cosmic rays within the atmosphere and Earth's surface.

The overwhelming majority of naturally occurring isotopes are *primordial*, formed in supernovae, and were well mixed before becoming the Earth's crust. This mixing resulted in uniform isotopic compositions for most of the elements found on Earth. However, some *radioactive elements* disintegrate spontaneously and become the nuclides of another element, creating as the result of their decay *radiogenic* isotopes of other stable elements at the end of their *decay chain*. For example, the element lead

has four naturally occurring stable isotopes, of which one, ^{204}Pb , is primordial, while the other three, ^{206}Pb , ^{207}Pb , and ^{208}Pb , are radiogenic endpoints of the decay chains of ^{238}U , ^{235}U , and ^{232}Th , respectively. The abundance of stable radiogenic isotopes increases with time, therefore a considerable number of naturally occurring elements have variable isotopic compositions in the Earth's crust.

The production of isotopes due to cosmic radiation is of importance for the lighter elements in the atmosphere like helium ($Z=3$) and carbon ($Z=6$), and in the rocks, for example, for calcium ($Z=20$). For the light elements, in particular, fractionation due to slight differences in their chemical behavior can modify the isotopic abundances of natural elements, for example in photosynthesis, which enriches ^{12}C over heavier ^{13}C .

Early investigations demonstrated that the elements with atomic numbers between 1 (hydrogen) and 83 (bismuth) have on average more than three stable isotopes, each in varying proportions. Bismuth is the heaviest element that is not radioactive. The nine naturally occurring elements with Z greater than 83 are naturally radioactive; they include polonium, thorium, radon, and uranium. Current research continues to provide accurate measurements of the isotopic compositions of the naturally occurring elements to give isotopic reference materials and the basis for determination of the standard atomic weights of the elements. A recently published report of the Commission on Isotopic Abundances and Atomic Weights (Berglund and Wieser 2011) provides a list of isotopic compositions of all 81 elements with stable isotopes from hydrogen to lead (excluding technetium, Tc) with the best measurements of their abundances on Earth. The number of stable isotopes for each of the elements depends on their atomic mass, but does not vary in a regular manner. For example, calcium ($Z=20$) has six stable isotopes, where the atoms of ^{40}Ca constitute 96.9 percent of this element, while copper ($Z=29$) has only two stable isotopes, ^{63}Cu and ^{65}Cu , of abundance 69.2 percent and 30.8 percent respectively.

The measurement of abundances of stable isotopes

The first instrumental observations of differences in isotopic abundances of elements were made by J. J. Thomson in 1914. Francis William Aston improved the design of this instrument using a magnetic sector instrument, and called it a "mass spectrograph". During his life Aston developed increasingly precise mass spectrographs with which he discovered 212 of 287 naturally occurring isotopes, also calculating for the first time more accurate atomic weights of elements. Aston was awarded the Nobel Prize in chemistry in 1922.

In the following decades, many scientists worked on improvements to this instrument. In 1940 Alfred O. Nier published a new design for mass spectrometers based on a 60° wedge electromagnet, and after World War II his workshop built a dozen such mass spectrometers for other scientists to use in isotope research. This development contributed enormously to the development of geoscience.

All current isotopic mass spectrometers consist of three basic components: the ion source, which forms a beam of charged ions from the analyte; an electrostatic or electromagnetic deflector to separate ions of different masses (most commonly a magnetic sector); and a collector of ions to measure the ion current. Isotopes of very low abundance can be measured using *accelerator mass spectrometry* (AMS), or mass spectrometers with a *gas source* (for example, for hydrogen or oxygen).

The isotopes of heavy elements (for example, strontium, copper, tin, lead, silver, uranium, thorium) can be accurately measured by two different types of instruments: thermal ionization mass spectrometers (TIMS) and multicollector inductively coupled plasma mass spectrometers (MC ICP-MS) (Niederschlag et al. 2003, 61–64). The major difference between these two types of instruments is in the type of source of ionization of atoms. TIMS relies on a solid source, while in MC ICP-MS the ions are produced in an inductively coupled plasma source. For reasons of accuracy, and for reasons related to the geochronological applications, the isotopes are measured not as abundances, but as ratios of two or more isotopes.

Many research laboratories are equipped with a cheaper instrument with an ICP source built for analyses of trace elemental compositions of materials, but capable of isotopic measurements, called a quadrupole inductively coupled plasma mass spectrometer (ICP-Q-MS); this instrument cannot produce data accurate enough for provenance research of archaeological materials (University of Texas at Austin 2017). The same is true for another technique that in principle can measure isotopic compositions: the time of flight mass spectrometers.

Sample materials for mass spectrometric isotope analysis need to be dissolved, therefore it is necessary to take samples of ancient artifacts and materials. When MC ICP-MS is used, there is also a possibility of using *laser ablation* for introduction of the atoms of the material into the source. This method can be used for particularly precious materials, for example gold.

Stable isotope fractionation

Isotopes of some elements do not show identical chemical behavior during mineral-forming processes; for example, copper and tin minerals show varied isotopic compositions due to the process called isotopic fractionation during crystal formation. These isotopic variations can, under certain circumstances, be used in archaeometallurgical research.

Laser-Induced Breakdown Spectroscopy (LIBS)

SALVATORE SIANO and JURI AGRESTI

Istituto di Fisica Applicata "N. Carrara" —Consiglio Nazionale delle Ricerche, Italy

Principles of laser-induced breakdown spectroscopy

Laser-induced breakdown (or plasma) spectroscopy (LIBS or LIPS) is a versatile analytical technique allowing the identification and quantification of atomic species composing a material through the spectral analysis of the plasma generated by its irradiation with a high-peak-intensity (above $\sim 10^8$ W/cm²) laser pulse.

A pulsed laser beam with pulse energy and duration of ~ 0.1 – 100 mJ and ~ 0.1 – 10 ns, respectively, is typically used in LIBS systems as an excitation source. Its focalization on a solid surface in a liquid or gas with a suitable lens produces ionization and then a rapidly expanding plasma plume, which appears to the naked eye as a bright spark. This optical emission represents the visible result of a complex superposition of photons, electrons, atoms, and ions interaction dynamics, which has been the subject of thorough investigations since invention of the laser in 1960 (Raizer 1977).

Let us consider the case of a solid material irradiated using the above-mentioned nanosecond laser pulses at typical peak intensities of $\sim 10^9$ – 10^{11} W/cm², which can be easily achieved by focusing the laser beam with a lens. This induces local vaporization, atomization, multiphoton ionization, and acceleration of free electrons by sequential absorption of photons through the so-called inverse Bremsstrahlung process.

When the kinetic energy of the electrons overcomes the ionization energies of the atoms under irradiation, new free electrons are created by impact ionization. Above a critical electron density (around 10^{13} el/cm³), under

sufficiently high photon flux, an avalanche electron multiplication is induced, which is referred to as optical breakdown. A rapidly expanding dense plasma region (10^{18} – 10^{21} el/cm³) is thus formed with typical associated temperatures and speeds of $\sim 10^4$ K and $\sim 10^4$ m/s, respectively. The plasma onset is followed by a pumping phase depending on the laser pulse duration and intensity. This develops according to a fluid dynamic interaction regime where the main ionization contribution is determined by collisions that extend the plasma lifetime well beyond the laser irradiation. The plasma parameters reach their maxima around the end of the laser pulse energy release; then quenching phenomena such as radiation emission, recombination, and other decay processes occur.

Laser-produced plasma emits optical radiation throughout its lifetime. During the onset phase this emission is dominated by the continuum spectrum of the electron Bremsstrahlung, which is not useful for material analysis purposes. Such a spectral contribution drastically decreases with the electron density after several hundred nanoseconds; then atom and ion electron transitions become predominant and their spectroscopic characterization becomes useful for elemental analysis (Cremers and Radziemski 2013). To this end, elimination of the former component represents a fundamental requirement that can be achieved by delaying the spectral acquisition with respect to laser irradiation. Spectroscopy within the present technique is hence carried out during the quenching phase of the laser-produced plasma, well after optical breakdown. This is the reason why some authors prefer to define the present technique as LIPS rather than LIBS, although the latter acronym is much more frequently used than the former.

From a technological standpoint, basically, a LIBS system includes the excitation laser source, focusing and collection optics, a pulse and delay generator, spectrometer (monochromator and sensor), and personal computer. In the schematic setup shown in Figure 1, the former is a Q-switched Nd:YAG laser, which is the

Figure 1 Schematic setup of LIBS.

most commonly used source, focused with the plano-convex lens L_1 . The plasma emission is collected by means of the lens L_2 (better if achromatic and aspheric) and coupled to the spectrometer through the optical fiber. The delay between the laser pulse and beginning of spectral detection (Δt) must be suitably selected in order to avoid the detection of the initial continuum emission. On the other hand, such a delay time should not be too long in order to avoid excessive cooling of the plasma and strong reduction of its luminescence, which would drastically reduce the signal to noise ratio (S/N). Often, time delays $\Delta t \approx 0.5\text{--}2\text{ }\mu\text{s}$ or, alternatively, corresponding shifts of the focal point of the collecting lens (L_2) are used.

The collection of the spectrum can be limited to a specific time interval (time gating) within the plasma lifetime or it can be longer than the latter. The former condition is useful when the hypothesis of local thermal equilibrium (LTE) is needed to measure the plasma parameters or to detect spectral lines with a relatively short lifetime. However, often short time gating is not a strict requirement and the typical free scan times of modern sensor arrays ($\sim 1\text{--}10\text{ ms}$) can be used. In this case, the accumulation time of the spectrum is determined by the plasma lifetime itself and its time of flight within the field of view of the collector, which typically varies between ~ 1 and $\sim 10\text{ }\mu\text{s}$.

A number of studies have reported on the dependence of the ablation and plasma dynamics involved in LIBS on laser wavelength and intensity aimed at optimizing the analytical

performance (see for example Fornarini et al. 2006). These pointed out that higher ablation rates and lower plasma temperatures are associated with ultraviolet–visible (UV–Vis) with respect to near infrared region–mid-infrared region (NIR–MIR) wavelengths, which is due to the inverse cubic dependence on the wavelength of optical penetration through the plasma region. Since higher plasma density, luminescence, and lifetime are usually preferable, NIR excitation sources such as a Q-switched Nd:YAG (1,064 nm) laser, including its more recent diode pumped version, are often used, although the experimentation has also included harmonics (532, 355, 266 nm), CO_2 (10.6 μm), and excimer (193, 248, 308 nm) lasers. Furthermore, since the beginning of this century, there has been a growing interest in ablative applications of femtosecond and picosecond excitation lasers, since they potentially provide better spatial resolution and absence of fractionation, although their advantages are still disputed.

As shown in Figure 1, individual lenses and optical fiber can be used for focusing the laser and coupling the plasma emission to the spectrometer. In this condition, the typical operative spot sizes range between about 10 and 200 μm . Moreover, LIBS is adaptable in microscopy setups using, for example, epi-axial coupling of the laser through the objective of the microscope, which replaces the lens L_1 , with consequent improvement of the lateral resolution up to the micrometric scale. Similarly, other optical components can replace the coupling lens L_2 .

Thus, in particular, a reflective collector using off-axis parabolic mirrors can be used to avoid problems related with the aberrations of a single spherical lens, and increase the repeatability of the measurements and reliability of portable devices thanks to its very stable setup (Agresti, Mencaglia, and Siano 2009).

The spectral resolution required for reliable LIBS analyses is relatively high (~ 0.1 nm) since atomic spectra of the materials are rather complex. In portable devices, this can conveniently be achieved using a set of ultra-compact spectrometers to cover the spectral range of interest. Such a class of low-cost instruments includes a Czerny–Turner monochromator and triggerable charge-coupled device/complementary metal oxide semiconductor (CCD/CMOS) sensor array, allowing delay of the acquisition with respect to its “trigger in” of Δt_1 . In some circumstances, if a given delay Δt_1 is set, a further intrinsic delay $\Delta t_0 \cong 0.3\text{--}1.5$ μs will be added by the sensor, which corresponds to the time needed for its reset. Thus, in those cases where delays $\Delta t \geq \Delta t_0$ provide a satisfactory optical signal, the spectrum detection can be triggered by the laser pulse itself (Figure 2a). Conversely, for relatively short lifetime plasmas and large Δt_0 , $\Delta t \leq \Delta t_0$ could be useful or needed in order to collect more signal. A simple solution is displayed in the example of Figure 2b, where an electro-optically Q-switched Nd:YAG excitation laser is considered: (1) the master trigger is generated and used to drive both the laser pumping and the spectrometer; (2) after a sufficient time, the QS triggering activates the laser and then the plasma emission; and (3) detection of the spectrum can be suitably delayed using the settable delay Δt_1 . In Figure 3, a detail of the spectrum of a ternary bronze sample is shown, which was detected about 600 ns after the laser pulse.

In laboratory setups, more sophisticated spectrometers have been often used, equipped with an echelle monochromator able to disperse the light in a wide range of spectral orders, associated with a time-gated and intensified CCD camera. This allows covering the whole range between 200 and 1,000 nm, setting precisely the delay (the triggering scheme of Figure 2a can be used by assuming $\Delta t_0 \cong 0$) and integration interval, and amplifying the signal up to a factor of 10^4 . These are fundamental features for increasing the sensitivity and

performing trace analysis. However, the costs of such spectrometers are much higher than those of the compact ones described above.

Finally, handheld LIBS devices with limited performances in terms of quantification and depth profiling are available on the market. These are based on miniaturized diode pumped solid state (DPSS) lasers with high pulse repetition frequency (~ 1 kHz), very low energy (~ 100 μJ /pulse), and pulse duration of $\sim 0.1\text{--}1$ ns, which reduces the problems related with the continuum spectrum component and then they can operate without triggering.

Besides the identification of the atomic species through comparison of the actual spectrum with the spectral fingerprints of the elements listed in databases (qualitative analysis), LIBS can be used to quantify them. As for other optical emission spectroscopic techniques, the basic assumption of the quantitative analysis is that the integrated intensities of the lines emitted by a given atomic species (analyte) are proportional to the species abundance in the plasma and hence in the material under analysis. However, besides the concentration of the elements and the response curve of the spectrometer, the intensity of a given emission line depends on other factors, such as the properties of the material and the complex interactions of the analyte within the plasma region (matrix effects), properties of the latter (temperature and electron density) associated with the specific irradiation parameters (wavelength, peak intensity, and pulse duration), and self-absorption. For these reasons, the most used approach to LIBS quantification is based on the measurement of relative rather than absolute integrated intensities. The ratio between the integral of a selected peak of the element to be quantified and the integral of a selected peak of the most abundant element (internal standard) is measured and the corresponding relative concentration is derived by comparison with a calibration curve. The latter can be achieved by fitting the intensity ratio of interest, as measured for a set of samples of known composition (i.e., known weight or atomic fractions). The reliability of LIBS compositional measurements strongly depends on the emission lines, which must be selected by evaluating their spectral purity, linear range of the calibration curve, and dependence on matrix effects.

Figure 2 LIBS triggering schemes: (a) laser emission used as a master trigger; (b) spectrum detection driven by an external master trigger (see text).

When the technique is used to achieve deep elemental profiles, dependence of the calibration curves on the crater depth should be taken into account. Thus, in general, a depth-dependent calibration surface should be used in these cases.

To avoid such a careful preliminary methodological optimization work, the so-called calibration-free (CF-LIBS) method has been sometimes used (Tognoni et al. 2010). Despite the reliability of this approach being strongly

Figure 3 Example of LIBS spectrum of a bronze sample.

questioned, it can be very useful for fast semiquantitative screening of complex materials where achievement of the calibration curves using reference samples is not easily practicable.

The minimum detectable content of a given element (limit of detection, LOD) is defined as the concentration, which corresponds to an intensity of 3σ , where σ is the standard deviation of the signal produced by a congruent blank sample. When using a calibration curve, $\text{LOD} = 3 \sigma/m$, where m is the slope of its linear stretch. The LOD of elements in different materials (matrices) can be found in the literature. Such limits depend on the instrumentation and operating conditions used and can vary from parts per million to hundreds of parts per million (see for example Appendix C in Cremers and Radziemski 2013). In general, LIBS systems equipped with intensified CCD sensors provide LODs lower than the corresponding ones of devices using nonintensified sensors. Moreover, it has been demonstrated that a further improvement of the sensitivity can be achieved using two excitation laser pulses separated by a suitable delay.

Finally, the reported accuracies of LIBS are usually about 5–10 percent, which are essentially determined by the intrinsic fluctuations of plasma dynamics and of experimental conditions.

Applications of LIBS

Although the analytical potential associated with laser-produced plasmas was recognized quite

early on since the beginning of the 1960s, the complexity of early laser sources and spectrometers did not allow concrete exploitation of LIBS up until the 1980s, when the novel technique started to be used in the environmental field in order to reveal the presence of contaminants. This step was helped by the technological advances of solid-state laser sources, holographic gratings, and precisely triggerable gated multichannel optical analyzers. Since then, LIBS has been extensively tested in various fields in all those material characterization problems where other elemental techniques such as atomic absorption spectroscopy (AAS), inductively coupled plasma with optical emission spectroscopy (ICP-OES), and scanning electron microscopy with energy dispersive spectroscopy (SEM-EDS) were already routinely used (Gaudiuso et al. 2010).

Early applications of LIBS in the field of cultural heritage were carried out during the early 1990s (Anglos and Detalle 2014). It is interesting to note that this applicative extension appeared almost simultaneously with the significant growing interest in the use of the laser as a conservation tool.

The main feature that has stimulated widespread applicative interest of LIBS in archaeometry concerns the possibility to perform rapid and relatively low-cost elemental analyses of any material directly on the object of interest, by avoiding invasive sampling, and time-consuming and expensive sample preparations, usually needed for traditional techniques such as AAS and ICP-OES. The minimal material ablation

involved and the availability of portable devices have made LIBS particularly attractive for archaeometrical applications, where the non-invasiveness and possibility to operate in situ can represent crucial factors whenever investigating valuable artifacts. Some of the studies reported in the literature have shown that also for the latter, exhaustive compositional maps can be achieved by collecting depth profiles from several tens of sites.

Thus, the microdestructivity does not represent a limitation in most of the cases of practical interest. As mentioned above, typical crater diameter ranges from 10 to 200 μm , while its depth strongly depends on the material under analysis. The ablation rate is a very variable parameter, ranging from the submicrometric scale of the metals to some tens of microns of the mortars. Such damage scales are usually acceptable also for relatively small artifacts, and even more when it is possible to perform the measurements in zones that are not visible in normal fruition conditions. Apart from the crater, which is almost invisible whenever LIBS is properly applied, sometimes the main problem could be due to the formation of a surrounding redeposition halo in the case of shiny surfaces. However, such a sort of stain can be minimized by reducing the energy and total number of laser pulses used, as well as completely removed with a soft mechanical action.

For archaeological objects, the redeposition effects are often negligible. Thus, within the present context, LIBS can be certainly considered a noninvasive technique (i.e., no relevant visible alteration effects are produced). This can be understood, for example, by considering that the mass needed for one traditional ICP-OES analysis of a metal alloy corresponds to some hundred LIBS depth profiles (sites analyzed) using about 2,000 laser pulses for each one.

Since the early 1990s, LIBS has been widely used for analyzing pigments, glasses, ceramics, and metals, even though the case studies reported are still relatively few. Routine material analyses for characterizing the state of conservation (see CONSERVATION) and approaching important archaeometrical problems still remain mostly based on traditional techniques, such as SEM-EDS, ICP-OES, and ICP-MS. Furthermore, the growing use of portable X-ray fluorescence (XRF) (see PORTABLE X-RAY FLUORESCENCE

SPECTROMETRY (PXRF)), which is a well-known nondestructive technique with a long development history, is not favoring the extension of LIBS within archaeometrical practice. However, the possibility of the latter to measure any element and to achieve compositional depth profiles with high depth and lateral resolutions can play a crucial role in important identification and quantitation problems.

The application perspective of LIBS for pigment recognition (see CHARACTERIZATION OF PIGMENTS) and characterization of glasses seems limited since these materials can be more easily analyzed using portable XRF and/or Raman spectroscopy (see RAMAN SPECTROSCOPY AND MATERIAL ANALYSIS). This holds also for most of the stratigraphic problems, where confocal XRF is providing interesting results, although some specific material superposition problems could justify the use of LIBS. The application perspective becomes more relevant in geochemical studies of stone artifacts, ceramics (see CHARACTERIZATION OF CERAMICS; ELEMENTAL ANALYSIS OF POTTERY; and NONDESTRUCTIVE COMPOSITIONAL ANALYSIS OF CERAMICS), and mortars (see CEMENTS, MORTARS, BINDERS) for general quantitative characterization purposes, as well as to identify the presence and assess the spatial behavior of specific elemental markers related, for example, to provenance and authentication studies or assessment of the conservation treatments. Finally, for metal alloy artifacts, LIBS offers unique performances and an exploitation perspective for investigating their complex surface deterioration stratigraphies and achieving representative bulk compositions (see DETERIORATION OF METALS and CHARACTERIZATION OF METALS AND ALLOYS). Relevance of this peculiar application has been thoroughly demonstrated in both statistical analysis of small archaeological findings (Fortes et al. 2005) and a number of archaeometallurgical studies of well-known Italian copper alloy masterpieces, such as the philosopher head of Porticello; the Arringatore from the environs of Lake Trasimeno; the Chimera of Arezzo; the bust of Emperor Antonino Pio; Alexander the Great Battling on Horseback; the sculptural groups by Giovan Francesco Rustici and Vincenzo Danti; the North Door by Lorenzo Ghiberti of the Baptistery of Florence; and

Donatello's St. Louis of Toulouse, Resurrection Pulpit, and David (Siano and Agresti 2015).

Mass Spectrometry (MS)

IGOR M. VILLA

Universität Bern, Switzerland; Università di Milano
Bicocca, Italy

General principles

In the early twentieth century, it was observed that gas ions accelerated in a cathode tube immersed in a magnetic field were deflected and impacted the glass wall of the vacuum tube off-axis relative to the case without the magnetic field. The radius of the curved trajectory depended on the ion's mass, as follows:

$$v = \sqrt{2qV/m} \quad (1)$$

where v is the ion's velocity, q its charge, m its mass, and V the accelerating potential; the ion's deflection is governed by the Lorentz force, F :

$$F = qvB \quad (2)$$

where B is the magnetic field intensity. The Lorentz force, the vector product of v and B , is perpendicular to both. The radius r of the curved trajectory is determined by the centripetal force F :

$$F = mv^2/r \quad (3)$$

Solving for r gives:

$$\begin{aligned} r &= mv/qB \\ &= \sqrt{m/q} \times \sqrt{2V/B^2} \end{aligned} \quad (4)$$

Aston (1922), examining noble gases in a cathode tube, noticed that neon surprisingly impacted the glass wall in two well-separated spots. He called the two spots of the same place-holder in the periodic table "iso-topes", that is, sharing the same place. The discovery of isotopes (see ISOTOPES) was followed over the years by the measurements of the isotopic composition of all elements using mass spectrometers.

Not all elements have constant isotopic compositions. Their variations can be produced by: (1) enrichment of a single isotope, the radiogenic daughter, due to radioactive decay of the parent isotope (this allows age determinations by geochronology); (2) monotonic, proportional enrichment/depletion of the lighter isotope(s) relative to the heavy one(s) of one and the same element. This natural mass-dependent fractionation (MDF) can have two causes. It can be either a kinetic effect (such as the slightly faster evaporation rate of an isotopically lighter liquid, or the partial uptake by living beings of an isotopically lighter molecule) or an equilibrium effect (such as the disproportionation of heavy/light isotopes in strongly/weakly bound molecules). Isotopic variations spawned a new branch of geology around 1950, isotope geochemistry, which relies on the continuous improvement of mass spectrometers.

An essential requirement of any mass spectrometer is a high vacuum. The mean free path of an ion under atmospheric pressure is $<0.1 \mu\text{m}$, which makes it impossible for an ion to travel straight from the source to the collector. If the pressure in the evacuated apparatus is 10^{-2} Pa (10^{-7} times the atmospheric pressure), the mean free path is 1 m. This means that in a mass spectrometer with a 1 m long flight tube, every ion has, on average, one collision with an air molecule between source and collector. Ions will reach the collector, but as every collision deflects the ion in an unpredictable way, the high collision probability makes measurements irreproducible. To achieve a measurement uncertainty lower than 10^{-4} , all systematic factors that could bias the result must be kept $<10^{-5}$, including collisions with air molecules. Less than one ion in 10^5 can collide with residual air. The vacuum required to ensure this mean free path is $<10^{-6} \text{ Pa}$.

Decisive improvements to mass spectrometer design were due to Nier (1940), who improved ion sources and optimized their interaction with the magnet that deflects the ion beam. In the most general terms, a mass spectrometer consists of three components: a source, a deflector, and a collection system (Figure 1).

Figure 1 Schematic representation of a mass spectrometer. The ion source is drawn here as composed of an ionizing filament and a number of plates that collimate and focus the ion beam. The deflector is drawn here as a magnet that deflects the ions as given by equations (1–4). The curvature radii r_L and r_H depict the circular sector trajectories of a light and a heavy ion, respectively. The two collectors drawn here are positioned so as to simultaneously acquire the light and the heavy ion beams. The whole flight tube (not drawn here for clarity), from the source to the collectors, must be kept in high vacuum ($p \ll 1 \mu\text{Pa}$) at all times. Note that all three components (ion source, deflector and collectors) do vary from the present general sketch in the different mass spectrometer types.

The ion source

The ion source creates, accelerates, and focuses the ions of the element to be measured. Different source designs are applied to different classes of problems, according to the respective capability of a source to ionize the elements of interest. In archeometric research, gas mass spectrometers (see below) are used for oxygen, carbon and nitrogen, which help constrain paleoclimate and human diet; TIMS and MC-ICP are used for Sr, Nd, and Pb, which help constrain the provenance of artifacts (metals, ceramics) and humans; AMS is used for ^{14}C and ^{10}Be geochronology; QMS-ICP is used for trace element concentration measurements in provenance studies (see below).

The first mass spectrometers, built a century ago, were suitable for the isotope analysis of rare gases and of O, C (as CO_2), N, and so on. In gas mass spectrometers, the ion source is a hot (1500–2000 °C) tungsten filament that emits electrons, which in turn ionize the low-pressure neutral gas that enters the flight tube. The positive gas ions are accelerated by a perforated plate having a negative potential of ca. 3–4 kV relative to the filament. Focusing the ion beam is achieved by a stack of several slits and half-plates, each having a potential difference of a few to a few tens of volts relative to the neighboring ones (a design dating back to Nier). The collimated ion beam then flies into the deflector.

Two factors control the total yield of ions that reach the collectors out of the number of neutral atoms that were let into the mass spectrometer source: (1) the ionization yield of the electron bombardment can be controlled by the filament current (i.e. the number of electrons) and the energy of the electrons, which are accelerated by an additional positive electrode; (2) the transmission yield of the (initially highly divergent) ion beam is never 100%, as most ions are accelerated at an angle with respect to the trajectory that eventually leads into the collector, and are implanted into the walls of the flight tube. As the multiple bending of the ions' trajectories by the focusing plates is a function of each ion's mass, it follows that the efficiency of focusing light ions into the collector is different from that of focusing heavy ions. Therefore, as a rule, the measured N_L/N_H ratio (where N_L and N_H are the numbers of ions with light and heavy isotopic mass, respectively) is different from the true N_L/N_H ratio in the sample, resulting in an artificial MDF. This effect is an intrinsic property of all sources that accelerate and focus an initially divergent ion cloud. Typically, it amounts to a few tens of percent per atomic mass unit (amu) and can be positive (preferential transmission of heavy masses) or negative (if light masses are favored). A reasonable assumption is that a source will cause a constant MDF as long as the tuning conditions of the plate stack are not changed due to electronic drift or retuning.

In rare gas mass spectrometers, the sample introduction is relatively simple: rare gases first need to be purified completely from all active gases (water, oxygen, methane, carbon dioxide, etc.), and then are introduced into the flight tube by completely opening an inlet valve and measured “in static mode” (i.e., the gas is left in the tube during the entire measurement and is pumped away at the end). A typical rare gas analysis lasts 10–20 minutes; shorter analysis times result in excessively high uncertainties, due to the low number of counted ions, whereas longer analysis times do not add precision due to the natural instabilities of the signal, caused by fluctuations in the spatial distribution of the gas in the source. In static mode, the gas is implanted into the walls of the flight tube and exponentially depleted with a time constant of a few ks.

In oxygen-type mass spectrometers (which also measure hydrogen, carbon, and nitrogen) the amounts of gas to be analyzed are much larger than in rare gas measurements (μmol as opposed to pmol), and static measurements are impractical. The measuring protocol differs from the rare gas protocol in two very important points: (1) the sample gas is leaked into the mass spectrometer through a very thin capillary, whose flow rate is carefully calibrated; the measurement is made “in dynamic mode”, whereby the gas is pumped from the flight tube at the same rate as the inflow; (2) to maximize the resolution of small isotopic differences between samples, each unknown sample measurement is bracketed by immediately preceding and following measurements of a reference standard of known isotopic composition. The mass spectrometer is equipped with a twin inlet, consisting of two identical capillaries, one for the sample, one for the reference standard, which are automatically switched by the measuring software. Each of the sample and standard measurements lasts for about 3–5 minutes.

In order to analyze non-gaseous elements, a different source is needed. The principle of a so-called thermal ionization mass spectrometer (TIMS) relies on releasing the ions of a solid element by slow vaporization, whereby a very small amount of the element of interest is deposited onto a thin ribbon of an ultrapure refractory metal (Pt, Ta, Re or W). Heating of the ribbon, also called filament, causes some of the evaporating atoms to become ionized and to

undergo MDF similar to that described above. The ionization and the mass fractionation of an element are affected by the presence of other elements on the filament; it is therefore mandatory to chemically purify the analyte.

One useful characteristic of thermal ionization is that each element has its own, distinct ionization temperature range. As a rule, volatile elements and elements with a low ionization potential are ionized both at lower filament temperatures and more completely than refractory ones. As an example, in a Rb-Sr analysis it can occur that the chemical separation of Rb from Sr was only 99% complete. The presence of ^{87}Rb would lead to isobaric interference and to an incorrect measurement of the $^{87}\text{Sr}/^{86}\text{Sr}$ ratio. However, fortunately for analysts, Rb is evaporated and ionized at lower filament temperatures than Sr. By a judicious choice of the filament heating protocol, all of the Rb can be boiled off before Sr emission starts, avoiding the isobaric interference.

Chemical purification of the element to be analyzed (mainly by chromatography; also by ligand extraction, distillation, or selective precipitation) leaves it as a soluble salt (chloride, nitrate, phosphate, etc.). In order to deposit the sample as uniformly as possible on the ionizing filament, the salt is taken up in ca. 1 μl of a loading solution and pipetted as close as possible to the center of the filament. As the filament is heated the ion beam will increase slowly to a maximum and remain stable for a time sufficient for a precise measurement. This time can vary between 10 minutes for a Pb analysis of single zircon grains, and over 10 hours for single-collector Nd analysis of crustal rocks. The analysis of refractory elements can be long and demanding; alternative analytical strategies require a plasma source. Some elements (e.g., Th, Hf) are exceedingly difficult to measure by TIMS, so that their use in isotope geochemistry and geochronology only became widespread after the invention of plasma sources.

Laboratory MDF can be corrected whenever the following assumptions are met: (1) natural MDF was negligibly small; (2) the element of interest has at least three isotopes, two of which are free of radiogenic daughter ingrowth and whose ratio is assumed to be fixed; or (3) the element only has two isotopes, and its MDF

behavior is identical to that of the bracketing standards.

MDF corrections use an empirical exponential law (Russell, Papanastassiou, and Tombrello 1978). The reason for resorting to an empirical correction, instead of a rigorous mathematical formulation, is that isotope fractionation is produced by concurrent but profoundly different effects: source fractionation, due to incomplete collimation of the beam by the focusing plates; Rayleigh fractionation, which occurs due to element evaporation from the filament; and inter-ion collisions. The relative importance of these effects changes as sample evaporation leads to a depletion of light isotopes in the residue. The bulk isotope fractionation in a measurement is the sum of these independent effects, each of which is sample-dependent and time-dependent.

Accelerator mass spectrometers (AMS) can be used to quantify very low isotope ratios, as are encountered in radiocarbon dating and cosmogenic isotope dating. As an example, the $^{14}\text{C}/^{12}\text{C}$ ratio of a 50 ka old sample is 10^{-15} . This requires control on systematic artifacts (e.g., tailing of the larger peaks, molecular interferences such as hydrides, etc.) of the order of 10^{-16} . This is achieved by an accelerating voltage of a few MV, provided by a tandem accelerator, and improved energy filtering of the beam.

Plasma source mass spectrometers (ICP-MS) achieve the complete ionization of a sample by a 7000–9000 K hot plasma, which ionizes all elements simultaneously. Two ICP-MS designs have evolved, in order to cope with the inherent chaotic instabilities of any plasma. They are the single-collector quadrupole (QMS) and the multi-collector double-deflecting sector, MC-ICP-MS. These design features are explained below. Both designs can be equipped with two different sample introduction systems: an aspirator-nebulizer or a laser microprobe. The former is used with previously dissolved samples; the solution can either be introduced, without further chemical processing, into a QMS (in order to determine element concentrations), or be processed first, so as to isolate a single element for isotopic composition measurements by MC-ICP-MS. The laser vaporizes a small sample volume, producing nanoparticles that are entrained by the carrier gas.

Accurate correction for mass-dependent fractionation of elements that have less than two

isotopes in a constant ratio is easier than in TIMS measurements. It involves a two-step procedure: first, the desired element is chemically purified; then, a different “dopant” element with a well-known isotopic composition and without isobaric interferences with the measurand is added to the solution. As all elements are ionized contemporaneously, the dopant provides the required constant isotope ratio. This offers a better reproducibility than measuring bracketing standards (which is limited by short- and long-term instrumental drift and imperfect chemical removal of matrix elements).

The deflector

Magnetic deflection has been in use since the 1910s. In order to transmit the ion with the desired mass into the collector, the deflection radius must be adapted, by tuning either V or B in Equation (4). Changing the accelerating voltage V often entails drifts and instabilities over several tens of seconds, whereas the hysteresis of modern electromagnets can be made shorter than 3 s. For increased resolution, a velocity filter consisting of an electric dipole deflector is inserted into the flight path before the magnet in AMS and MC-ICP-MS (“double-focusing”).

An alternative to magnets producing curved (circular sector) trajectories is the electric quadrupole. Its electric field deflects the ions into spiraling trajectories that hit the flight tube walls, except for ions having one single m/q value that follow a rectilinear path into the collector. By changing the field intensity, it is possible to successively collect any ion with any m/q value. As the quadrupole field hysteresis is $\ll 1$ ms, electric quadrupole deflectors can be made to scan the mass range of interest in the ms range. This is useful in ICP sources: plasma instabilities (which modify the transmission of ions) occur on longer timescales. The entire periodic table can be scanned in less than 1 s. The reproducibility of ICP-QMS element concentration measurements can be optimized to reach 1% by repeating the scan a sufficient number of times to average away the plasma instabilities. For isotopic composition measurements, a 1% precision is insufficient, but trace element studies have been revolutionized by this technique.

The collection system

The early mass spectrometers were equipped with a single collector, into which the ion beams were sequentially deflected by “peak jumping”. Quadrupole mass spectrometers still operate like this, as only one ionic species is transmitted for a given quadrupole field. The other instruments described above nowadays have multiple, simultaneously operating collectors, such that peak jumping is possible but no longer required.

The most widespread collector is the Faraday cup (FC), a passive component consisting of a cup connected to a high resistance (0.1–10 TΩ); when positive ions hit the cup, electron currents (in the fA–pA range) flow to compensate the charge imbalance. The resulting potential at the ends of the resistance is measured. Metrological calibrations document the high linearity, and low associated systematic uncertainty, of modern FC circuits.

The factor hampering universal use of FC collectors is their sensitivity, as the signal/noise ratio is limited by the electronic noise of the amplifier. For very weak signals (aA–fA, i.e., 10^{-10} – 10^{-14} ions per second) an active component, the ion counter (IC) or secondary electron multiplier, offers better detection limits. The IC consists of a front plate which emits electrons when hit by an ion. These secondary electrons are accelerated by a voltage of ca. 2 kV and successively hit a cascade of dynodes, producing a short-lived charge avalanche that triggers a counter. It is possible to measure count rates between a few Hz and around 1 MHz, as the background count rate can be made quite low and the signal/noise ratio correspondingly high. However, ICs also have limitations: the dynamic range is 4–5 orders of magnitude at most; their linearity is no better than 1%, and is variable over time; and the FC/IC gain depends on the measuring conditions and is difficult to determine precisely.

Perspectives

Applications are addressed in detail in other chapters. Here, potential and limitations of mass

spectrometric analyses in archaeometry are briefly mentioned.

Isotopic compositions are more suitable as negative evidence, ruling out a provenance, rather than as firm, positive identifiers, since many potential sample sources (ore deposits, food supplies, pottery clays, etc.) can share similar geological/climatic histories and therefore record very similar isotopic signatures. Provenance studies require unravelling a broad context of multiple isotopic systems, ideally supplemented by laser-ablation ICP determination of geochemically significant trace element ratios (compare with Villa, 2016).

Metallography

DAVID A. SCOTT

University of California, Los Angeles, USA

Metallography as a science has its origins in the nineteenth century, particularly with the investigations of Henry Clifton Sorby (Sorby 1864), who first cut and polished specimens of metals and thought of etching the resulting structure to reveal their morphological characteristics. A microscope suitable for metallography is called a metallograph and the light path is arranged such that the light source impinges through the lens onto the polished metal surface and the reflected rays are then passed back through the lens where a half-silvered mirror directs the light to the eye-piece. Metallographic microscopes are usually equipped with polarizing light capabilities and often with differential interference contrast (DIC), both of which are useful in the metallographic examination of archaeological artifacts.

Metallography is extremely useful for investigations into the fabrication technology of ancient metals (Smith 1965), as well as issues related to authenticity and authentication. In the case of some artifacts, preservation goals concerning the retention of the original may preclude any invasive treatment if the artifact is extensively mineralized or precious, and many advanced techniques are available for examination of some aspects of microstructure without taking a sample at all, such as neutron radiography (see NEUTRON RADIOGRAPHY AND TOMOGRAPHY), or crystallographic texture analysis (see METALLOGRAPHY AND CRYSTALLOGRAPHIC TEXTURE ANALYSIS), which has been used to examine the microstructure of the copper axe used by the Bronze Age Iceman found in the Swiss–Italian Alps (Artioli 2007).

The practice of metallography usually involves the removal of a small sample from the object concerned. It is, however, possible to polish part of an edge or selective area of a surface of an object to obtain the desired information. Conventional

X-radiography (see X-RAY RADIOGRAPHY) can provide useful information concerning manufacturing techniques and has been of great utility in metallurgical studies of ancient iron, in particular (Scott and Eggert 2009). Structural information as to whether the object has been worked to shape or cast can be seen on an X-radiograph, and the heterogeneous nature of iron artifacts made from bloomery iron can be discerned and different components examined. In some cast bronze alloys, the dendrites can even be seen on the X-radiograph and radiographic pairs can be used to image the interior of castings, allowing casting porosity, location of core pins, spacers, or chaplets to be revealed.

Methods for removal and mounting of small samples have been reviewed by Scott (1991). Examination of the polished section can utilize the light microscope (see OPTICAL MICROSCOPY), preferably a metallograph, and samples can be placed in the electron microprobe (EPMA) for quantitative analysis, or in the scanning electron microscopy (SEM) for semiquantitative analyses or imaging; analysis usually employs energy-dispersive X-ray analysis (EDXA), while imaging may utilize either secondary electron imaging (SEI) or back-scattered electron imaging (BEI), or environmental scanning electron microscopy (ESEM), or be analyzed with X-ray fluorescence (XRF) (see X-RAY FLUORESCENCE SPECTROMETRY (XRF)) techniques, all of which are invaluable in a comprehensive study of metallographic sections.

It is possible with large objects, or with the edges of coins, to polish selected areas of objects to examine the metallographic structure in situ, in cases where it may be impossible to cut or remove a section from the object. Microstructural features may be selectively etched or pseudomorphically preserved on metallic surfaces, which allows this technique to reveal micromorphology directly. A list of etchants suitable for archaeological artifacts is given in Scott (2011).

When mounted samples are studied, the surface of the metallic specimen should be examined first in the freshly polished state, followed by

etching with a suitable etching reagent. There are often severe restrictions on the quantity of metal that can be removed from an artifact for metallographic examination, especially nonferrous metalwork. Care must be taken with very small samples to ensure that they are not lost in the process of grinding and polishing.

A number of criteria should be considered before any sampling is undertaken: (1) The microstructure of the samples should not be altered in the process of removal. (2) The sample should be representative of the object as a whole or of a selected feature or area of the object. (3) The orientation of the sample in its dimensional relationship to the object concerned should be marked on a photograph or a drawing of the object. (4) If it is not obvious from where the sample was taken, the position on the object concerned should be marked on a photograph or a drawing of the object. (5) The sample should be assigned a laboratory number together with sufficient documentation to enable its identity to be preserved. (6) The object should be photographed or drawn before the sample is taken. This is especially important if the dimensions of the object are fundamentally altered by the material removed.

The range of features that may be made visible in prepared samples is variable, depending on the type of specimen examined and how it is prepared; detail not apparent using one etchant may become visible only after another reagent has been employed. The following are some of the major microstructure features that can be examined: (1) The range and the type of grains present. Their size can be compared with an eye-piece marked with grain sizes for comparison or with American Society for Testing Materials (ASTM) standard grain size numbers. ASTM grain size numbers range from 10 (very small) to 1 (large). Further details concerning grain size are discussed by Vander Voort (1999). The ASTM has produced a very useful reference document which should be consulted for further information (ASTM 2009). Any cracking, loss, or inclusions present at grain boundaries should be noted. (2) The presence of different phases which can be observed either in the corrosion crust or the metal. The presence of different phases is an indication of how the overall composition of the artifact relates to its actual microstructure. Gross

heterogeneity or differences between various areas of the sample should be noted, especially in the case of iron and steel artifacts. The order of magnitude of the scale of these differences may range from several millimeters to a few tens of microns. (3) The grain shapes or surface deformation features or heat-treated zones at cutting edges and worked surfaces. Metals are crystalline solids and the grains may preserve indications as to how they have been treated or affected by heat. (4) The distribution of inclusions, weld lines, slag particles, or porosity and the volume fraction of pores and holes. (5) The presence of any surface coating or gilding. Sometimes, careful examination at high magnification is necessary to establish the presence of surface coatings, lead gilding, amalgam gilding, tinning, and so on. (6) The distribution of any corrosion products present and the existence within corrosion layers of pseudomorphic remnants of grain structure or other microstructural features, remnant metallic grains, and layering or unusual features. (7) Indications of grain-boundary thickening or precipitation of another phase either within the grains themselves or at the grain boundaries. (8) The presence of twin lines within the grains and whether these are straight or curved. In face-centered cubic metals, such as copper, silver, and gold alloys, these are common. (9) The presence of stain lines within the grains; these are common in copper and bronze alloys. (10) Whether dendrites (a structure that is common in cast alloys and which may look like an intersecting snowflake pattern) shows indications of coring and the approximate spacing, in microns, of the dendritic arms, if these are clearly visible. (11) The size and shape of any nonmetallic inclusions present in the metal. Most inclusions cannot recrystallize at the temperatures at which archaeological metals are worked or cast, usually less than 1,200 °C, and they become elongated or broken up along the direction of working of the metal. (12) The presence of intercrystalline or transcrystalline cracking in the polished section. This is frequently related to working techniques employed during manufacture, or subsequent stresses experienced by the artifact as a result of burial or corrosion.

Further details concerning many aspects of metallographic preparation can be found in Scott (2011) and Van der Voort (2004). Color etching

(a)

(b)

(c)

(d)

(e)

(f)

(Scott 2014) may be particularly revealing for the metallography of ancient metals, because the technique is especially good at helping to preserve the corrosion crust, often etched away in conventional etchants, and for revealing effects of segregation, which many ancient metals exhibit.

Metallography and microstructure

Some examples of the application of metallography are given here. The cross-section of a Luristan dagger from Iran reveals the extent of the differences between the hilt of the dagger itself, seen in Figure 1a, which is embedded in the cast-on bronze handle shown in Figure 1b. An extensive amount of corrosion has occurred between the junction of these two components, resulting in large amounts of redeposited copper. The casting-on process has annealed and partially recrystallized the hilt of the bronze blade, which can be seen in Figure 1a. The pronounced dendritic segregation of the higher-tin bronze alloy used to make the handle can be clearly seen in Figure 1b.

Figure 1b shows a low-magnification view of the handle itself. It is a typical cast high-tin bronze microstructure which clearly illustrates the dendritic segregation of the melt. The arms of the dendrites are copper-rich and are cored, with darker etching zones around the perimeter of the dendrites. These etch darker here because the tin content is higher than in the center of the dendrite arm. Surrounding the dendrites is an extensive infill of the $\alpha + \delta$ eutectoid phase of the bronze, which etches a pale blue-gray.

Examples of Thai high-tin bronzes are shown in Figures 1c and 1d, revealing not only the complex microstructure of these bronzes, but also the survival of the metastable beta-quenched acicular phase within the corrosion crust of these bronzes for over 2,000 years. The revelation here is that these high-tin bronzes were shaped by hot-working and were quenched from about 700 °C in order to retain the beta phase of the bronze system and to prevent the precipitation of the $\alpha + \delta$ eutectoid, which while chemically the same in terms of overall bronze composition, would give completely different working properties. The $\alpha + \delta$ phase precipitation results in the slow-cooled bronzes

Figure 1 (a) Color-etched photomicrograph of a Luristan bronze dagger and hilt. Composition of the dagger itself is 83.6 percent copper, 13.5 percent tin, 0.3 percent iron, 0.8 percent lead, 0.4 percent arsenic, 0.6 percent nickel, with zinc and silver not detected. This is an excellent choice as too much delta phase would make the blade hard but brittle. (b) Color-etched photomicrograph of a section through the cast-on handle of the same dagger. Small clumps in the structure which can just be seen here are redeposited copper. Uncorroded eutectoid appears white while corroded eutectoid is a darker gray. Composition is 76.6 percent copper, 20.8 percent tin, 0.9 percent lead, 0.5 percent nickel, with zinc, iron, and arsenic not detected. (c) Color-etched photomicrograph of a copper alloy bowl from the site of Ban Don Ta Phet, Thailand, showing dendritic alpha phase with infill of acicular beta. Microstructure reveals the bowl is cast, reheated, and then quenched. Composition is 21 percent tin, 79 percent copper. (d) Color-etched section through a bronze bowl from Ban Don Da Ne, Thailand, from the Bronze Age, showing the acicular beta phase, and twinned alpha in a background of beta phase. There is a considerable scatter of white copper sulfide inclusions present. Composition about 20.5 percent tin, 79.5 percent copper. Twinned alpha phase here reveals that the bowls have been cast, reheated, quenched, hot worked, and then quenched again, before turning on a lathe to produce the cut decoration seen. (e) Photomicrograph of an electrotyped artifact in the collection of the Victoria and Albert Museum, London, showing directional solidification and long columnar grains which often characterize copper and copper alloys deposited from solution; compare with Figure 1f. Etched in alcoholic ferric chloride, composition is 100 percent copper. (f) Electrotpe from the 1880s in the collection of the Victoria and Albert Museum. Etched in alcoholic ferric chloride, showing a series of rather fine twinned grains. This is not the usual kind of morphology associated with electrotyped copies and shows the considerable variation which is possible.

Figure 2 (a) Polarized light view of a photomicrograph of part of the surface of a copper plaque from collections of the Johan von Wagner Museum, Stuttgart. The mid-gray of the cuprite, its penetration into the remaining copper, and the outer lighter gray corrosion products of malachite are all acceptable for authenticity of the plaque. Unetched section. Composition of the plaque is 98 percent copper, with small amounts of arsenic, lead, nickel, and antimony. (b) Scanning electron photomicrograph taken on a Cambridge Instruments electron microprobe showing the remnant metallic structure of a Chinese bronze mirror of the Tang dynasty, composition 77 percent copper, 21 percent tin, and 3.5 percent lead. Bright white spots are of uncorroded lead, dark black spots are corroded lead, light gray are alpha regions and some cuprite, darker gray background is the corroded eutectoid phase of alpha + delta. (c) Cross-section through a Chinese bronze mirror from the Warring States, composition 24 percent tin, 4 percent lead, 72 percent copper. Color etched to show the fine microstructure of the alpha and alpha + delta eutectoid. An advantage of this etching procedure is that it preserves the corrosion crust rather than attacking it, allowing the entire structure to be seen under polarized light.

being very brittle. The quenching of these high-tin bronzes enabled them to be cut with a lathe and turned, which is also not possible with the normal high-tin bronze alloys.

Artifacts produced from copper solutions as electrotpe copies of the original were often made in the period 1850–1910 as exact replicas of metallic or other artifacts. It may be possible to distinguish these copper replicas from original artifacts using Laue back-scattered X-ray

diffraction techniques which produced a series of Debye–Scherrer rings with many electrotypes due to the very small grain size of deposited copper. It is the grain structure of these artifacts that is essential here, and this can be determined by metallography. The lowest energy deposition methodology for copper deposited from solution is to produce a series of columnar grains, with twinned grains common, and often occurring across the contiguous columnar crystals.

Figure 1e is a good example of directional precipitation of copper from solution in an historic electrotype from the Victoria and Albert Museum made around 1870. This structural morphology is never found in ancient copper alloys, and is distinctive for an electrotype copy.

Figure 1f illustrates the microstructure of another electrotype from the Victoria and Albert Museum, in which the twinned crystal structure of the object dominates the matrix of the deposited grains.

An interesting case is that of a Greek plaque from the ninth century BCE, of considerable importance for the history of the development of the alphabet. The plaque is made of quite pure copper, and has preserved pseudomorphic mineralized wood fragments on the surface. These can also be seen in a more rudimentary form in metallographic cross-section and are potentially important associations with the burial context of the plaques. Figure 2a illustrates a polarized light view of part of the corrosion crust of one of these plaques. The use of criteria based on the corrosion products in terms of providing evidence of authenticity has been studied since the 1950s.

Corrosion may penetrate considerably into what appears superficially to be a quite sound metallic matrix. A good example is shown in Figure 2b: a high-tin bronze Tang mirror. In the uncorroded state these mirrors frequently display a Widmanstätten precipitation of the eutectoid phase, which does not conform to the remnant microstructure seen in Figure 2c. Figure 2c does not reveal this kind of microstructure. From this we could conclude that the optimal microstructure was not attained in this example, and that it displayed more of the alpha phase in a principally cast orientation, even if not dendritic.

The fabric of the mirror shown in Figure 2b has been seriously weakened by corrosion so that parts of the artifact are prone to crumble at the edges. Figure 2c shows the etched microstructure of a mirror from the Warring States, where there is a residual Widmanstätten pattern to the delta phase, set in a rather corroded alpha matrix. Just at the boundary between the original surface of the bronze and the overlying corrosion products, some small patches of redeposited copper can be seen, a common feature in many ancient Chinese artifacts. The Widmanstätten morphology here is

due to the cooling rate of the bronze as well as its composition. Bronzes with 25 percent tin often crystallize as a cellular structure rather than a collection of dendrites.

Metallographic studies should be integrated as far as possible with archaeological data, provenance, chemical composition, and technology of manufacture to extract the maximum benefit from the removal of a small sample from the object.

Microarchaeology

MICHAEL B. TOFFOLO

Université Bordeaux Montaigne, France

Microarchaeology is the study of the microscopic archaeological record, that is, everything that cannot be seen by the naked eye and therefore requires the use of instrumentation. Initially used in a purely archaeological acceptance to indicate the description of small, but visible fragments of cultural material, the term “microarchaeology” now refers to a branch of archaeology that was developed since the 1980s as a result of the application of analytical methods to the characterization of archaeological materials and sediments. This approach stems from the integration of the natural sciences with archaeology aimed at solving archaeological problems, and is based on immediate on-site analyses during fieldwork and detailed laboratory work, geared towards a better understanding of past human behavior.

Since the 1940s, the need for more detailed determinations of archaeological activity areas and building functions brought archaeologists to work on progressively smaller fragments of cultural material, such as food remains or chips resulting from the breakage and use of tools and architectural features. These fragments of waste material are embedded within occupational debris on living surfaces and in most cases undergo little displacement through trampling or post-depositional processes. For these reasons, small fragments were supposed to be the only cultural remains in primary deposition, and therefore truly representative of the human activities that took place at a specific location (e.g., Cook and Treganza 1947). In the following decades the collection methods saw improvements, and the term “microarchaeology” appeared in the early 1970s to define the study of minute fragments of artifacts and other cultural material recovered through sieving and flotation of sediments from occupational deposits (e.g., Archaeology Correspondent, 1973). However,

this subdiscipline of archaeology deals mostly with the visual identification and quantification of small remains (usually larger than one millimeter), and not with their chemical characterization in relation to the depositional context and ultimately the human activities that produced them. In fact, it is known today as “microartifact analysis” (Sherwood 2001).

Recently, “microarchaeology” became the standard term to define the study of the archaeological information hidden within sediments and artifacts, at the microscopic scale and below, with the aid of instruments such as microscopes and spectrometers. This change in meaning did not evolve from an improvement of microartifact analysis; rather, it is the result of a tradition of scientific archaeology that finds its roots in nineteenth-century Denmark. There, C. J. Thomsen and J. J. A. Worsaae developed the three-age system and the chrono-typology of artifacts using a scientific, predictive method that can be reproduced with different materials in different geographic areas. Their approach complemented work of G. Cuvier, C. Lyell, and J. Lubbock based on the principles of paleontology, geology, and evolution, thus laying the foundations of modern archaeology (Trigger 1989). However, despite chemists analyzing ancient artifacts since the eighteenth century, the scientific approach had little impact on archaeological method and theory until the mid-twentieth century. This situation changed completely with the radiocarbon dating revolution brought about by W. F. Libby (Libby, Anderson, and Arnold 1949). This global breakthrough in archaeology not only provided an independent check for relative chronologies based on chrono-typology of artifacts and ancient texts, but also created absolute chronologies. Moreover, it built a strong bond between the natural sciences and archaeology, and thus promoted the application of a large number of analytical methods to the study of archaeological materials, in particular those belonging to the microscopic record. For instance, since the late 1970s special attention has been devoted to the study of microstratigraphy using sediment micromorphology

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0377

(see MICROMORPHOLOGY) and X-ray diffraction (XRD), in order to better characterize natural and anthropogenic formation processes (see FORMATION PROCESSES). It is within this framework that present-day microarchaeology was established by S. Weiner in the 1980s, with the first systematic studies of mineral and bone assemblages in prehistoric cave sediments using an on-site laboratory (Weiner and Goldberg 1990). At the same time, microarchaeology gained momentum from its overlap with the field of biomineralization, which focuses on understanding the processes used by organisms to mineralize their tissues (Lowenstam and Weiner 1989). Phytoliths, bones, teeth, dung spherulites, mollusk shells, eggshells, and diatoms are all biominerals commonly found at archaeological sites. They are often directly related to human activities, and in some cases they record paleoenvironmental settings. Thus, the ability to identify and describe these components, and how they end up in archaeological deposits, is a crucial step for the correct interpretation of archaeological contexts and past human behavior. The interaction between microarchaeology and biomineralization dramatically expanded the amount of information that can be obtained from the archaeological record. At present, microarchaeology has been successfully employed at several sites from different periods and regions of the world.

The goal of microarchaeology is to answer archaeological questions by extracting information from the archaeological record below the submillimeter scale. This includes the materials of which the macroscopic artifacts and archaeological features are made, as well as the sedimentary matrix in which the artifacts are found. To do so, microarchaeology makes use of analytical methods that address different aspects of the microscopic record, depending on the research question at stake. Such methods encompass, but are not limited to, the techniques employed in archaeometry (see ARCHAEOOMETRY), geoarchaeology (see GEOARCHAEOLOGY and SOIL CHEMISTRY IN ARCHAEOLOGY), paleogenetics (see ZOOARCHAEOLOGY AND ANCIENT DNA and DNA: NEXT GENERATION SEQUENCING), archaeobotany (see PALEOETHNOBOTANY; PALEOETHNOBOTANY AND ANCIENT DNA ANALYSIS; PALEOETHNOBOTANY AND STABLE ISOTOPES; and PALYNOLOGY), zooarchaeology (see ZOOARCHAEOLOGY;

ZOOARCHAEOLOGY AND HUMAN DIET RECONSTRUCTION; ZOOARCHAEOLOGY AND HUMAN TRADE AND MIGRATION; and ZOOARCHAEOLOGY AND STABLE ISOTOPES), geochemistry (see HUMAN SKELETAL GEOCHEMISTRY and PALEOENVIRONMENTAL RECONSTRUCTION), and absolute dating (see DATING IN ARCHAEOLOGY), and are aimed at reconstructing the formation processes of archaeological contexts (see FORMATION PROCESSES), the manufacturing processes of artifacts, and their transformations due to post-depositional alterations (see TAPHONOMY). Particular attention is dedicated to the study of diagenesis (see DIAGENESIS OF BONE), which may alter the original mineral assemblages of sediments and artifacts and therefore lead to misleading interpretations. Only pristine organic and mineral components may be used for archaeological purposes. On the other hand, the absence of specific minerals or categories of artifacts, such as bone, or the presence of diagenetic minerals, can help determine whether archaeological contexts are affected by diagenesis, which in turn might be driven by changes in environmental conditions of archaeological importance. Results are then integrated with the information obtained from the study of the macroscopic record (architectures, artifacts, bones, burials, installations, etc.) to reach a better understanding of past human activities and therefore of the archaeological record as a whole.

The macroscopic and microscopic records are part of the same entity, and, as such, they should be investigated at the same time. Therefore, as with all archaeology, microarchaeology starts in the field with the identification of an archaeological problem. In order to answer a specific question, data are gathered during excavation, analyzed, and in light of the results, the original question is reformulated, according to a scientific method. Considering that archaeological excavations are destructive operations, it is useful to characterize the relevant contexts before they are removed using an on-site laboratory, which can provide results within minutes or hours, depending on the method. This is a key step in microarchaeology, as it provides invaluable contextual information regarding the archaeological problem that would otherwise go lost. It also helps in reducing sample size and costs, as opposed to “blind” sampling of the entire

site. In addition, it forces archaeologists with different backgrounds (macro versus micro) to discuss problems and the strategy to tackle them, and confront each other as work is in progress, finding a common basis for communication. By spending weeks together in the field, experts in the microscopic record can understand all the subtleties regarding archaeological contexts, whereas experts in the macroscopic record realize the potential applications and limits of analytical instruments. The setup of the on-site laboratory may include a Fourier transform infrared (FTIR) spectrometer for the qualitative characterization of chemical phases in artifacts and sediments (see INFRARED ABSORPTION SPECTROSCOPY (IR, FTIR, DRIFT, ATR)), a bench X-ray fluorescence (XRF) spectrometer for the quantification of metallic compounds (see X-RAY FLUORESCENCE SPECTROMETRY (XRF)), a petrographic microscope for the analysis of mineral and organic components in sediment smear slides (see OPTICAL MICROSCOPY), a binocular microscope for the analysis of microartifacts, a dry-sieving apparatus for the recovery of small charred materials, and the gear for phytolith and phosphate extraction (see PHYTOLITH ANALYSIS and SOIL PHOSPHATE CHEMISTRY, respectively). Results are obtained in real time and interpreted in comparison to a set of control samples that help in differentiating the archaeological context under investigation from the sediments surrounding it. These results contribute to a better overall understanding of the site. With this new information, the original question can be refined or rejected, and the excavation strategy is adjusted accordingly. A new round of sampling may be carried out for immediate analysis, or a full set of samples may be collected for more detailed research at the home laboratory after the end of the excavation. There, samples may be analyzed using time-consuming methods such as sediment micromorphology (see MICROMORPHOLOGY), and nonportable instruments that can provide characterizations at the molecular and atomic level, such as XRD, Raman micro-spectrometry (see RAMAN SPECTROSCOPY), FTIR micro-spectrometry (see INFRARED ABSORPTION SPECTROSCOPY (IR, FTIR, DRIFT, ATR)), scanning electron microscopy with energy dispersive spectrometry (SEM-EDS), mass spectrometry for stable isotope analysis, accelerator mass spectrometry for radiocarbon

dating, gas chromatography-mass spectrometry (GC-MS) for the analysis of organic residues (see ORGANIC RESIDUE ANALYSIS), and thermogravimetric analysis (TGA). The choice of methods and instruments should be tailored to the original research question.

Besides answering specific archaeological questions, laboratory work may lead to major discoveries. The occurrence of apparently inconspicuous or previously unnoticed components and features in sediments and artifacts may trigger the development of new analytical procedures, or the improvement of established methods, with fundamental implications for both the natural sciences and archaeology (e.g., Regev et al. 2010; Toffolo and Boaretto 2014). In this sense, microarchaeology is a constantly expanding discipline, with much room for improvement. Progress takes place not only through technological advancements in instrumentation developed for other disciplines, such as geochemistry and biology, but also with the application and refinement of known procedures, thanks to the diversity of the archaeological record. With a growing demand for better precision and accuracy in the characterization of archaeological materials, it can be predicted that in the near future new methodologies will be developed specifically to solve archaeological problems. This will be the result of training archaeologists in both the natural sciences and archaeology, who will be able to study the archaeological record in its entirety, going from the macroscopic to the microscopic and back.

Micromorphology

PAUL GOLDBERG

University of Wollongong, Australia; University of Tübingen, Germany; Boston University, USA

Micromorphology is the study of undisturbed samples of soil, sediment, and archaeological materials (e.g., adobe) at the microscopic level (Courty, Goldberg, and Macphail 1989), generally using polished slabs of the material and petrographic thin sections (see OPTICAL MICROSCOPY). The fundamental essence of the technique relies on the fact that the context and the original position of the components are preserved, permitting the identification of primary (depositional) events and processes (e.g., sedimentation of natural or human origin) from post-depositional ones, such as soil formation (and its associated processes), human trampling, or remobilization of the material being studied.

Micromorphology has its roots in soil science, dating to the publication of *Micropedology* by Kubiěna (1938), which sets out a series of guidelines for systematically observing and describing the coarse and fine components in the soil in order to understand soil genesis. Since the late 1930s and into the 1980s, micromorphology was generally practiced by soil scientists who concentrated on soil genesis/classification, mineral weathering, paleopedology, and agriculture, among others (Stoops 2014). Although Cornwall (1958) was among the first to use micromorphology in an archaeological context, it was not until the 1980s that micromorphology really began to be applied to archaeological issues (Courty et al. 1989). Its overall practice in soil science has declined since the beginning of this century, although its use in archaeology and sedimentology has increased substantially during this interval (Stoops 2014).

“Archaeological micromorphology” (which is the implied use for “micromorphology” in this entry) has a more inclusive approach than that of “soil” micromorphology: It is broader

in scope and examines geogenic and anthropogenic deposits, and archaeological materials (e.g., adobe, mortars, plasters), and its goals comprise—among others—landscape and paleo-environmental reconstructions, human constructions, past human activities, past behaviors (e.g., agricultural practices, pastoralism), pyrotechnology, and the suite of physical and chemical changes that modify archaeological deposits (diagenesis); many of these processes in aggregate can be subsumed under the rubric of “archaeological site formation” (see FORMATION PROCESSES).

Whatever the goal, micromorphological investigations start with thorough, well-documented fieldwork, especially careful examination and documentation of the site’s context, geomorphic setting, and site microstratigraphy (see ENVIRONMENT AND LANDSCAPE; ENVIRONMENTAL ARCHAEOLOGY; and GEOARCHAEOLOGY); good field photos of the deposits showing location of the micromorphological and associated samples help guide thin section observation and interpretation. Archaeological deposits are complex and exhibit a large amount of vertical and lateral lithological variability and interstratification at a site or within a structure, particularly when the anthropogenic components and human activities are prevalent, such as in Neolithic and later period sites—tells and mounds. In order to account for this inherent variability in the field, Courty (2001) extended the concept of facies from geology to include that of microfacies, which helps keep track of localized differences in depositional and post-depositional processes. In doing so, it provides a bridge from field observations to those made under the microscope.

In light of the undisturbed nature of micromorphological samples, the original geometry of the components (both solids and voids) has to be maintained. These blocks can be collected in several ways (Goldberg and Macphail 2006): (1) cutting them out from a profile of compact material and wrapping them tightly with tissue and tape; (2) inserting drainpipe or metal boxes into a section (so-called Kubiěna boxes); or (3) encasing the blocks with bandages impregnated

with plaster of Paris. In the laboratory, the unwrapped blocks are either air- or oven-dried (generally around 40–60 °C) for several days; for clayey materials, water may be removed by freeze-drying or acetone replacement. The sample is then impregnated with resin—typically epoxy or unpromoted (i.e., accelerator-free) polyester resin—preferably under vacuum in order to ensure better penetration of the resin into the sample, particularly for clayey samples. Good results can be achieved for nonclayey samples after a gel-time of just a few days. The hardened blocks are then sliced with a rock saw and appropriate areas within the slices are selected and trimmed to the final appropriate size of the thin section. Unlike slides typically used in sedimentary petrography (27 × 46 mm), those in archaeological micromorphology are larger so as to incorporate the inherent heterogeneity of archaeological deposits and features within a slide. Dimensions of finished thin sections vary from 50 × 75 mm up to 140 × 68 mm. The trimmed blocks are ground flat on one surface, glued to the thin section, and then ground and polished to a thickness of 30 µm. The thin sections are left uncovered to permit subsequent analysis by other microanalytical techniques (Goldberg and Macphail 2006).

In tandem with the collection of blocks, small bulk samples (~200 g) are collected from microstratigraphic units for other analyses (e.g., X-ray diffraction (XRD), bulk chemistry) (see RAMAN SPECTROSCOPY). As a caveat, in measurements from bulk samples, one is not certain what is being analyzed: calcite from original deposition of limestone versus secondary precipitation of calcite from roots, or speleothems.

Thin sections are studied optically with stereo- and petrographic microscopes at magnifications from 1 to 500× using plane-polarized (PPL), cross-polarized (XPL), and dark field illuminations; ultraviolet (UV) and cathodoluminescence are particularly useful tools for examining diagenesis. Whereas petrographic microscopes are needed to document mineralogy or small components such as phytoliths, low-magnification observation is essential to document the microstructure and the organization of the different materials in the sample, that is, the fabric, and the thin sections should be

observed alternately and repeated at these different microscopic scales. A good flatbed scanner can produce high-resolution scans of both the thin sections and the polished slabs from which they are made. In addition, thin sections or parts of the slabs can be studied with scanning electron microscope (SEM) or electron microprobe at several thousand times magnifications to examine crystallinity, diagenesis, and elemental composition (see DIAGENESIS OF BONE AND ELECTRON BACKSCATTER DIFFRACTION (EBSD)).

Micromorphological observations are similar to those used in sedimentary petrography and should be comprised of objective attributes. For coarser grains (i.e., sand, larger sizes) these include mineralogical and organic composition, abundance, size, and shape of grains, and sorting (distribution of grain sizes). For the finer matrix (generally silt and clay) the internal organization is noted (b-fabrics), which in XPL is displayed by the birefringence and extinction patterns: well-oriented clay, for example, will show parallel extinction, whereas randomly oriented particles will have a speckled appearance. At a higher level of observation is the porosity/microstructure (e.g., crumbly, platy, etc.).

In addition to these individual components and fabrics are features that are essential to understanding the history of a deposit. (1) *Sedimentary features* concern sediment source, mode of transport, and deposition of clastic grains. Deposition creates sedimentary structures, such as bedding and surface features (e.g., ripple marks). (2) *Pedologic and post-depositional features* refer to modifications of existing materials by biological, mechanical, or chemical processes. Examples include aggregation of material by burrowing or as excrements, coatings of clay in voids or around grains, and the precipitation of oxides, carbonates, and phosphates in voids or as nodules. (3) *Anthropogenic features* are produced by human activities and represented by ashes, charcoal, bone, organic matter, lithics, pottery, and construction materials; at a higher order of organization these can take the form of hearths or walls, for example.

Since archaeological deposits are lithologically highly variable, a single thin section can be quite complex and many differences can be observed from top to bottom, commonly occurring as

microstratified layers (i.e., on the order of centimeters) of different compositions, structures, and so on. In addition, some of the layers may be present in different thin sections from the same vertical sequence or in different parts of the site. Thus, it is best to try to categorize these layers into microfacies in the sense of microstratigraphic units visible and definable within a thin section (Flügel 2009). Applying this concept obviates the need to describe the same units repeatedly and at the same time significantly improves the ability to interpret the deposits as a whole, both from within a thin section and up to a reconstruction of formation processes at the site scale.

At the interpretative level, the microscopic observations as an ensemble can lead to a comprehensive understanding of the sum total of geogenic and anthropogenic deposition, as well as physical and chemical post-depositional processes. The former might include trampling, reworking of sediment by dumping, middening, or hearth formation and cleaning, whereas the latter might entail dissolution of limestone or bone, or the precipitation of secondary minerals such as phosphates that reflect diagenesis and environmental conditions at the site.

It should be emphasized that micromorphological investigations of thin sections using optical microscopes are just the starting point, and there are analytical limits governed in part by the thickness of the thin section and the size of grains. Although SEM/microprobe has traditionally been used to assess mineralogical and elemental composition, more recent approaches make use of the context preserved in the thin section to analyze specific grains and make inferences of the temperature of heating of bones and clays, for example, types of organic matter, and so on. Techniques include micro-Fourier transform infrared (FTIR) and Raman spectrometry, micro-X-ray fluorescence (XRF) and XRD (Mentzer and Quade 2013).

This “in-situ analysis” is a relatively recent development and it illustrates one of the major advantages of micromorphology: the original “micro” context of all components is preserved and can be related to their actual position in space (the microcontextual approach of Goldberg and Berna 2010). Micromorphology in this way serves as a methodological filter whereby thin section observations point the way to subsequent

specific analyses to answer questions not resolvable with optical microscopy (e.g., what is the mineralogy of a certain precipitated mineral or grain—aragonite versus calcite?).

Lastly, in addition to new analytical instruments and methods, ethnological approaches have been used to improve the quality of micromorphological interpretation (e.g., Shahack-Gross 2011) (see ETHNOARCHAEOLOGY). All of these approaches further our ability to understand the natural and human history occurring at an archaeological site.

Mössbauer Spectroscopy

LUCA NODARI

CNR-ICMATE, Italy

In the first half of the twentieth century, the nuclear emission and absorption of γ -rays, leading to subsequent γ -ray fluorescence, was only predicted but not demonstrated. The main difficulty in experimental demonstration was due to the existence of the nuclear recoil, which accompanies both the γ -ray emission and absorption in free nuclei. In fact, the energy involved in the nuclear recoil process inhibits the resonant absorption in a free nucleus, and therefore γ -ray nuclear fluorescence cannot be revealed. In 1958, a young scientist, Rudolf Mössbauer, published his first paper demonstrating that a nucleus in a solid matrix can sometimes emit and absorb γ -rays without recoil. In a solid matrix the nucleus is no longer isolated, but is fixed in the lattice, which minimizes the recoil process. In this condition, nuclear resonance fluorescence can be detected. This phenomenon, known as the Mössbauer effect, or recoilless nuclear resonance fluorescence, is the core of Mössbauer spectroscopy (MS). In 1961, Mössbauer, at the age of 32, was granted the Nobel Prize for his work on recoilless nuclear resonance.

The occurrence of a recoil-free event depends not only on the vibrational properties of a solid, but also on temperature, nuclear lifetime, and energy of the nuclear γ -ray. The last phenomenon delineates the Mössbauer effect only to a certain nuclide. These nuclides should possess excited nuclear states with lifetimes in the range of ca. 10^{-6} to 10^{-11} s, and transition energies between ca. 5 and 180 keV. ^{57}Fe is the most suitable nuclide; other frequently used nuclides are ^{119}Sn , ^{121}Sb , ^{123}Eu , and ^{197}Au . Investigations on nuclear resonance fluorescence led to the development of nuclear spectroscopy. MS probes slightly change the energy levels of a certain nuclide as a consequence of the interactions between the nuclide itself and its chemical environment. MS provides

both chemical and structural local information about a specific nucleus embedded in a solid matrix. It is a solid-state technique and it is used as an investigation tool in most of the disciplines of natural and applied science, such as nuclear physics, chemistry, mineralogy, metallurgy, and, of course, archaeometry.

In the traditional setup, the spectrometer is formed by two basic components: a proper source of γ -rays and the detector, usually a proportional counter or a scintillator. The solid sample, conveniently powdered, is placed between the source and detector. In order to have the effect, the source and sample (defined also as the absorber) contains the same Mössbauer active nucleus. That is, different absorbers need different sources: An ^{57}Fe absorber needs a source that can generate γ -rays with the proper energy to promote nuclear resonance fluorescence. With ^{57}Fe , the source is ^{57}Co , which transforms, by electron capture, in the metastable ^{57}Fe in the $5/2$ nuclear excited state. The thus-generated excited nucleus decays spontaneously to the $1/2$ ground state via a γ -ray cascade which includes the decay from the excited $3/2$ level to the ground level. This process emits the 14.4 keV γ -radiation necessary to excite the ^{57}Fe nuclei in the absorber from the ground state to the $3/2$ excited state, giving rise to the Mössbauer effect. A similar process is involved for other nuclides. The γ -rays not absorbed in the sample are counted by the detector, resulting in a transmission spectrum. Because the resonance lines are extremely sharp (10^{-9} eV of the natural line width for ^{57}Fe in comparison with 14.4 keV of the emitted rays), the energy has to be modulated to obtain the resonance. The γ -rays energy can be modulated by a first-order Doppler effect, thus applying a relative motion to the source. For this reason the abscissa is expressed in millimeters per second; in ^{57}Fe a velocity of a few millimeters per second guarantees the resonance condition. The spectrum thus obtained consists of a series of absorption lines, the positions and intensities of which give the Mössbauer fingerprints of the studied material. In general, the total absorption

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0392

intensity is a function also of the concentration of the Mössbauer nuclei, allowing semiquantitative analysis of the population in the different sites. Analysis of the absorption lines results in the hyperfine parameter, which quantifies the interactions between the nucleus and the environment. These parameters are: isomer shift, δ , quadrupole splitting, Δ (or ϵ when magnetic coupling is present), and magnetic splitting. Concerning magnetic splitting, only the contribution of internal magnetic field B , arising from the intrinsic magnetic property of the absorber, will be hereafter discussed.

Isomer shift, known also as the chemical isomer shift, is the result of a Coulomb interaction between the nucleus and the electronic charge density over its volume. It represents the difference in total electron density at the nucleus between the sample and standard, similar to the chemical shift in nuclear magnetic resonance (NMR) (see NUCLEAR MAGNETIC RESONANCE (NMR)). Therefore δ has to be expressed relative to a standard absorber; concerning ^{57}Fe , the standard is $\alpha\text{-Fe}$. In the spectrum δ is the displacement of the signal from the zero, as will be discussed below. In general, total electron density at the nucleus is affected by any variation in the number of electrons, or their distribution, in the valence shell. Therefore, with a certain nuclide in a specific matrix, a variation in δ reflects a change in the oxidation state. Furthermore, since the distribution of electrons on valence orbitals affects the electron density, δ is representative of high/low spin (hs/l_s) configurations. δ depends also on the relative change in nuclear radius between the excited and the ground state, which can be positive or negative, depending on whether the nucleus expands or contracts during decay to the ground state. In the case of ^{57}Fe there is an expansion in nuclear radius after the decay, that is, δ increases, decreasing the oxidation state. On the contrary, ^{119}Sn has a contraction in nuclear radius after decay, and thus δ decreases, decreasing the oxidation state.

Quadrupole splitting, Δ , describes the effect of the electric charge distribution on the nucleus (precisely the electric gradient field generated by the charge distribution on the nucleus). When a nonspherical charge distribution is present, the excited nuclear level loses its degeneracy, giving rise to a splitting in the lines, the so-called

doublet. The charge distribution is the sum of the lattice contribution (thus an external contribution with respect to the nucleus) and that due to bonding and/or nonbonding electrons, so variation in Δ reflects variation in the single contributions. With the exception of ionic systems, the contribution of the lattice is negligible in comparison with that resulting from bonding and/or nonbonding electrons, which mainly affect Δ . Variations in the charge distribution, for example due to a different site geometry and/or to various substituents and/or to a difference in the second coordination sphere, promote a variation in Δ . If the charge distribution is spherical, as when the site geometry is cubic and all the ligands are identical, the excited nuclear level preserves its degeneracy and the spectrum consists of a single line, a singlet, whose displacement from zero is δ . Conversely, when the charge distribution is nonspherical, as when the site geometry decreases in symmetry or when different ligands are coordinated to the same nucleus, the spectrum consists of a doublet. The center of gravity of the doublet corresponds to the δ , while the distance between the two minima corresponds to Δ . For instance, when two different structural sites are present, the spectrum shows two doublets characterized by different δ and Δ , whose intensities are representative of the population in the two sites. At the same time, a variation in Δ is observed when sites with the same geometry but chemically not equivalent are present. For instance, ^{57}Fe MS can easily discriminate Fe(III) from Fe(II), and the different coordination of both species, in clayey minerals. Fe(II) shows a δ higher than Fe(III), typically ≈ 1 mm/s instead of ≈ 0.35 mm/s.

The last hyperfine parameter originates from the magnetic dipole interaction between the nuclear magnetic moment and any magnetic fields acting on the nucleus. When a nucleus is placed in a magnetic field, the degeneracy of both ground and excited nuclear levels vanishes, resulting in magnetic splitting, and a multiplet (Zeeman splitting) is observed in the spectrum. With ^{57}Fe , the 3/2 excited level is split into four levels, while the 1/2 ground level is split into two, so six transitions are allowed, resulting in a sextet. The separation between line 1 and 6, the external lines, results in the intensity of B . B values are expressed in Tesla (T). As for δ and

Δ , B values quantify the local interactions at the nucleus, allowing a detailed description of the magnetic properties of the materials. With ^{57}Fe , the discrimination between hematite ($\alpha\text{-Fe}_2\text{O}_3$) and goethite ($\alpha\text{-FeOOH}$) can be on the basis of B . In both cases, Fe(III) occupies octahedral sites, but the former shows a B of approximately 51.7 T, while the latter shows a B of about 38 T. It is worthy to note that ^{57}Fe MS can support diffraction, especially when multiphase mixtures, containing tiny amounts of iron oxides, are analyzed. For instance, when studying pottery (see ELEMENTAL ANALYSIS OF POTTERY and POTTERY DATA QUANTIFICATION) MS can differentiate quite easily between magnetite and maghemite, two spinels whose formation depends on the firing atmosphere. These phases show similar X-ray diffraction (XRD) patterns, and the correct attribution could be tricky because of the large contribution of the other phases to the diffractogram. On the contrary, MS discriminates the two phases due to its sensitivity to local Fe interactions. Magnetite (Fe_3O_4) shows a spectrum with two distinct sextets, attributable to the tetrahedral and the octahedral Fe site in the structure. The two sextets differ for δ , Δ , and B values; tetrahedral ferric sites show the highest B , 49.2 T, and the lowest δ , 0.26 mm/s. The octahedral sites present parameters intermediate between Fe(III) and Fe(II) , indicating a charge transfer significantly faster than the Mössbauer time window (10^{-9} s). Conversely, maghemite ($\gamma\text{-Fe}_2\text{O}_3$) shows only a broad sextet, whose parameters are typical of Fe(III) in octahedral geometry (δ close to 0.36 mm/s and B close to 49 T).

For their intrinsic properties, hyperfine parameters are temperature dependent. In general, decreasing the measurement temperature below room temperature (usually at liquid nitrogen temperature) is normally preferred. First, the temperature decreasing increases the “rigidity” of the system, that is, it increases the number of recoilless events, improving the Mössbauer effect. Simultaneously, the different temperature dependence of the hyperfine parameters allows a better spectral resolution. Another relevant aspect of low-temperature experiments concerns the study of nanosized iron oxide. These species, due to magnetic properties connected to their small dimension, usually show a

doublet at room temperature and are indistinguishable from paramagnetic compounds. This phenomenon, known as superparamagnetism, is suppressed, lowering the measurement temperature. For instance, nanosized hematite (≈ 8 nm in diameter) shows a doublet at room temperature which transforms in a sextet at ≈ 77 K. On the other hand, microcrystalline hematite particles show a well-resolved sextet at room temperature.

Traditional experiments are performed in transmission mode; however, MS can be performed in backscattering mode, collecting conversion electrons (conversion electron Mössbauer spectroscopy (CEMS)), X-rays, and γ -rays that leave the absorber. Working in backscattering geometry allows noninvasive analysis on the “surface” of the sample. The investigated thickness changes from several hundreds of nanometers (≈ 200 nm) in CEMS to tens of microns by detecting X- and γ -rays.

The application of MS to archaeological materials allows an in-depth characterization of the material and it is particularly useful when the Mössbauer nucleus is used as a probe to understand the interaction of the material with the environment—that is, to study firing technology. It is successfully applied to investigate pottery, vitreous materials (see CONSERVATION OF VITREOUS MATERIALS and DETERIORATION OF VITREOUS MATERIALS), metallic artifacts, slag (see ORE AND SMELTING SLAG), pigments (see CHARACTERIZATION OF PIGMENTS), and inks (see INK). Almost all the literature is focused on investigation with ^{57}Fe ; there are few circumstances in which ^{119}Sn and ^{197}Au are used. Among the above-mentioned materials, clay-based ceramics are the most studied, thanks to the relatively high amount of Fe contained. Iron occurs in many silicates and oxides, and it changes easily its oxidation state as a result of environmental variations. It is therefore an ideal probe to understand pottery firing conditions. Since the pioneering works, MS has been used to estimate Fe(II) and Fe(III) content in pottery in order to understand the kiln's redox conditions. Moreover, it is used to link the Fe oxidation state to the pottery's color, especially when Fe(II) is present. In fact, grayish-dark hues can be related to the presence of Fe(II) -bearing minerals such as hercynite (Fe_2AlO_4) and/or to magnetite. Hercynite shows a doublet, whose

parameters are typical for Fe(II) in octahedral sites, while magnetite shows the magnetic pattern described above.

MS is particularly useful to follow the chemical and mineralogical transformation of iron-bearing minerals during experimental firing under controlled conditions. Literature data demonstrated that variations in Δ can be related to the chemico-physical transformation of the mineralogical assemblage during firing. It was observed that dehydroxylation of clay minerals, occurring between 400 and 600 °C, promotes a drastic increase in quadrupole splitting, while the formation of new phases, at higher temperature, involves a decrease of Δ values (Wagner and Kyek 2004). The information obtained by MS can be used as support to evaluate the firing temperature. To understand the nucleation and growth processes of iron oxides in pottery and to relate them to pottery coloration, low-temperature measurements are necessary. For instance, a coloring mechanism involved during the firing of carbonate-rich clays was proposed by Nodari et al. (2007). Comparing the data obtained at room temperature, representative of microcrystalline hematite, with those obtained at 80 K, representative of both macro- and nanocrystalline hematite, the authors explained the pale colorations of high fired calcareous pottery. It was shown that at temperatures higher than 900 °C, the 80K magnetic pattern increases in relative area, indicating an increment in nanosized hematite versus coarser-grained hematite particles. The presence of nanosized hematite, dispersed in a Ca-rich amorphous phase, affects the pottery's color. In fact, at the same firing temperature, Ca-rich findings usually show a creamy or brownish hue, contrary to the intense red/orange color shown by carbonate-free pottery.

The redox condition in glass (see GLASS AND FAIENCE and GLASS COLOR) manufacturing can be studied by MS. Since iron is almost regularly present in ancient glasses, as a result of impurities or intentionally added as colorant, it can be used as a probe for determining the redox conditions in the glassy matrix. This is particularly true when iron is the only chromophore. In such conditions it is possible to associate the color with the Fe(II)/Fe(III) ratio, that is, with the redox condition of the furnace.

Analyzing ancient mixed-alkali vitreous findings, it was observed that oxidizing conditions, with an Fe(II)/Fe(III) < 0.5, promote a dark-yellow coloration. The hue is attributable to octahedral and tetrahedral Fe(III) sites rather than the presence of nanosized ferric oxides. In nonoxidizing conditions, with an Fe(II)/Fe(III) > 3.0, a blue color is obtained, as a result of the presence of a large amount of Fe(II) in octahedral sites (Artioli et al. 2009). Between these Fe(II)/Fe(III) ratios, glasses show a green-bluish coloration, and Fe is distributed over octahedral and tetrahedral sites. It is interesting to point out that some findings with an unusually high amount of Fe(II) show an amber coloration. Atomic absorption analyses show the presence of Fe only as chromophore, together with a non-negligible amount of sulfur. MS reveals the presence of a significant amount of Fe(II) ($\approx$ 80% in relative area), whose parameters are distinctive for Fe(II) in 1s configuration (Bianchin et al. 2005). This suggests the presence of Fe-S adducts, which impart the typical amber hue.

In order to understand the nature of Au nanoparticles in eighteenth-century ruby glasses and the role of Sn in Au nanoparticle formation, a series of ^{197}Au and ^{119}Sn Mössbauer experiments were performed on mock-up samples by Wagner et al. (2000) and Haslbeck et al. (2005). The samples were prepared by adding to soda-lime glass and/or sodium silicate glass various amounts of Au and Sn, as KAu(CN)_2 and/or HAuCl_4 and SnO_2 , respectively. The raw materials were melted at 1,400 °C, quenched, and, at a later time, annealed between 500 and 700 °C. After the annealing procedure the ruby color strikes, as a result of the formation of Au nanoparticles. The presence of Au(I) and Sn(IV) and Sn(II) was observed in the quenched colorless glass, while Au(0) and Sn(IV) were detected in the annealed glass. It was observed that only the presence of Sn in raw materials promotes the formation of a large fraction of small Au nanoparticles enhancing the ruby color. On the basis of Mössbauer data, the role of Sn(II) as a reducing agent was proposed: The formation of Sn(II) during melting promotes the reduction of Au(I) to Au(0), and the subsequent formation of gold cluster during annealing.

Nanoarchaeology

JOSEFINA PÉREZ-ARANTEGUI

IUCA—Universidad de Zaragoza, Spain

To know what a nanomaterial is has been one of the most discussed questions in recent years. In fact, in 2011 the European Commission published a recommendation (2011/696/EU) to propose a nanomaterial definition to determine when a material should be considered a nanomaterial for regulatory purposes in the European Union. Currently, the EU recommends the following definition of the term: “*Nanomaterial*” means a natural, incidental or manufactured material containing particles, in an unbound state or as an aggregate or as an agglomerate and where, for 50% or more of the particles in the number size distribution, one or more external dimensions is in the size range 1 nm–100 nm. This definition is based exclusively on the size of the constituent particles of a material, where “particle” means a minute piece of matter with defined physical boundaries. This is an example of the complexity of the subject, and other international standardization organizations are in constant discussion and revision of the term.

In this current frame, advances in the use of very sophisticated analytical techniques have collaborated to understanding the structure and composition of many ancient materials, and the results have demonstrated the surprising presence of nanomaterials in these early objects, thus explaining many of their properties. “Intentionally manufactured” or not, just as the new nanomaterials, these products have been present since antiquity with similar features to those currently created.

Nanoparticles in vitreous materials (glass and glazes)

The most frequently described object where nanoparticles are present in its structure is the

famous Lycurgus Cup (see GLASS AND FAIENCE and GLAZES, SLIPS, AND PAINTS). It is one of the most technically sophisticated glass objects made before the modern era. Historically it belongs to a type of Roman vessel called “cage cups” and is generally dated to the fourth century CE. The object is especially known for the unusual optical properties of its glass, the so-called dichroic effect: The glass looks like jade with an opaque greenish-yellow tone in direct light, but it turns to a translucent ruby color in transmitted light. Although the cup came to scholarly attention quite early, it was in the late 1980s when the examination of a small fragment by transmission electron microscopy (see TEM AND ARCHAEOLOGICAL MATERIALS) (TEM) demonstrated the presence of minute particles of metal (50–100 nm in diameter)—a silver-gold alloy with a ratio of about 7:3 (containing also about 10% copper) inside the glass matrix and responsible for the dichroic effect (Barber and Freestone 1990).

In fact, it is well known that the presence of small particles of metallic gold is responsible for the red-ruby color of glass. The art of producing gold ruby glasses goes far back in time, at least to the Roman period. Some researchers suggest it dates back to the seventh century BCE, where Assyrian clay tablets (see CLAY TABLETS) mention a recipe allowing the production of “an artificial coral.” The red-ruby pigment was cited as early as the ninth century by Islamic scholars. In 1546, Agricola talked in his *De Natura Fossilium* about how Venetian glassmakers used gold to tint the glass ruby red. In the seventeenth century, gold ruby glass manufacture seems to have developed, when “Purple of Cassius” (a colloidal suspension of gold obtained by reducing a gold (III) chloride aqueous solution with stannous chloride) was added to the glass batch compositions.

Still more ancient glass technologies already exploited the presence of metal particles in the glass matrix to produce red color. As early as 1500 BCE, copper red glass was manufactured in Egypt. In Europe, red glass colored by copper dates from the late Bronze Age (1200–1000 BCE) in Italy. “Hematinum” red glass was first described

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0400

by the Roman historian Pliny the Elder; it is an opaque glass colored by particles of a size with the same order of magnitude as the wavelength. The origin of the color in copper red glasses has been debated, with some authors stating that it is due to metallic copper (Cu) nanoparticles, while others state that it is due to Cu_2O nanoparticles or to both. Electron microscopy observations have demonstrated that the copper particles are less than $0.5\ \mu\text{m}$ across.

Another element used to color glass because of its potential nanodimensions was silver. The decoration of glass using silver pigments appeared in the early Islamic world (eighth century CE) and they were later introduced in the preparation of European medieval glasses. In the silver stained glass, the yellow coloration is the result of the formation of silver nanoclusters. During the glass manufacture, metallic silver aggregates and it forms spherical crystals with a diameter between 1 and 100 nm. Depending on the size, shape, and particle size distribution, these nanoparticles affect the final color of silver stain.

Actually, these metallic nanoparticles were used worldwide. For instance, we can also find glasses colored by copper in Satsuma Japanese objects (nineteenth century, Edo period) and in ancient Thai decorations. Even this type of metallic pigment was not limited to glass manufacture and they were also introduced to produce colored glazes on ceramics in ancient times. The secret of the Chinese blood-red “Sang de Boeuf” or Lang yao hong pottery (eighteenth century, Qing dynasty) was the presence of copper in the glaze, and a similar technique gave rise to the red “flambé” and mixed blue-red Jun glazed porcelains from the middle-aged Song and Ming to Qing Chinese dynasties, as well as some Vietnamese porcelains and stonewares. Moreover, the use of gold in a similar recipe to the “Purple of Cassius” was present in China in the manufacture of the “Famille Rose” porcelain (eighteenth century) and in the French workshops of Sèvres to produce gold-based purple colorants, like in “Rose Pompadour” glazing.

However, one of the most investigated glaze decorations based on the presence of metallic nanoparticles is luster (Figure 1). It is a type of ceramic decoration, which results in a beautiful metallic shine and colored (golden, yellow, red) iridescences on the surface of the ceramic object.

Figure 1 Transmission electron microscopy (TEM) image of metallic silver nanoparticles embedded in a glaze producing a golden luster decoration (Syrian luster ware).

Source: Reproduced with permission from Pérez-Arantequi et al. 2004.

The earliest luster was probably made in Iraq in the early ninth century CE on tin-glazed ceramics, but the technology spread from the Middle East to Persia, Egypt, Spain, and Italy. Analytical electron microscopy revealed that luster ceramic decoration was the first manufactured nanostructured metallic thin film (Pérez-Arantequi and Larrea 2003). It is formed by a homogeneous surface microstructure composed by small quasi-spherical clusters embedded in the glaze, with a usual total thickness of 200–500 nm of this structure, in any case, less than $1\ \mu\text{m}$. The clusters are metallic copper and/or silver nanoparticles, with diverse diameters (less than 50 nm), and sometimes arranged according to different sizes from the outer to the inner layers.

Additionally to these elements, in ancient Jian wares (Song dynasty, 960–1279 CE), famous for their lustrous black glaze that exhibits unique colored patterns, a scientific study (Dejoie et al. 2014) identified iron oxide crystallites in the brownish-colored “Hare’s Fur” strips: a mixture of $\alpha\text{-Fe}_2\text{O}_3$ (hematite) and the metastable $\varepsilon\text{-Fe}_2\text{O}_3$ phases. The $\varepsilon\text{-Fe}_2\text{O}_3$ there consisted of randomly oriented sub-100-nm-size crystals dispersed within the glaze below the surface.

Nanomaterials in pigments

Maya blue was first produced by the Mayas in Mesoamerica about the eighth century CE, and extended well into the colonial era as late as the twentieth century, widely used in mural paintings, ceramics, and codices. The pigment is extremely stable and it has a bright turquoise hue; its remarkable properties have attracted the efforts of many researchers to explain and justify Maya blue features over decades. Since the publication of the paper by José-Yacamán et al. (1996), Maya blue can be also considered among the ancient nanostructured materials. The pigment belongs to this material category because of its structure and composition, combining palygorskite (a clay) and indigo (an organic dye). Using TEM, the painting samples showed regions containing well-shaped crystals of palygorskite, but with a superlattice and then a period of about 14 nm, explained because impurities (indigo molecules) are stacked inside the pillared structure of the clay. However, there were also other regions in the samples with a substrate of amorphous SiO_2 that contained metal nanoparticles, most of them identified as Fe and Cr, but also Mn, Ti, and V, sometimes in a metallic state and others as oxides (i.e., $\alpha\text{-Fe}_2\text{O}_3$), and probably with strong interactions between the nanoparticles and the SiO_2 substrate. The presence of these metallic impurities and their oxidation or encapsulation, together with the indigo molecules encapsulated in the clay pores, would be among the reasons for the acid-resistant property of the pigment and its color. Later studies justified the formation of Maya blue on the basis of the indigo adsorption only in the “grooves” of the palygorskite, instead of inside their channels (Chiari et al. 2008). Besides, palygorskite structure itself has dimensions close to nanomaterials (the fibers have a diameter range from 140 to 200 nm and length from 1.2 to 2.8 μm).

As well as nanostructured Maya blue, at present, other ancient pigments like Egyptian blue (formed by calcium copper tetrasilicate ($\text{CaCuSi}_4\text{O}_{10}$), quartz, and amorphous silica (SiO_2)) are being considered because of their possible nanodimensions. The facile exfoliation of bulk $\text{CaCuSi}_4\text{O}_{10}$ into nanosheets (two-dimensional nanomaterial) and the strong

near-infrared (IR) emission preserved in these exfoliated samples made this pigment very promising in modern technochemical applications (Johnson-McDaniel et al. 2013). Similar behavior could be expected from Han blue, a barium copper tetrasilicate ($\text{BaCuSi}_4\text{O}_{10}$).

Other nanomaterials in ancient objects

In metals, the comparison of the structure of seventeenth-century Damascene steel blades showed a common feature, responsible for their extraordinary mechanical properties. In spite of the different microstructures, colonies of wire- and tube-like particles with diameters of 40–50 nm were observed by high-resolution TEM (see TRANSMISSION ELECTRON MICROSCOPY); the main phase forming these particles was crystalline cementite (Fe_3C), covered by carbon nanotubes (Reibold et al. 2006).

Another study by TEM evidenced a nanocrystalline structure in an ancient metal mirror alloy, a Cu-32 wt% Sn alloy that had been made by an age-old crafted casting process. Within the dendritic regions, a preponderance of quasi-crystalline nanoparticles, typically with size less than 10 nm, was observed (Sekhar et al. 2015). Bronze mirrors of high tin composition have been manufactured for around 4,000 years and probably the earliest use was in China.

A completely different illustration of ancient nanomaterial is that used to dye hair black since the Greco-Roman period. As a consequence of the chemical treatment, synthesized galena (lead sulfide) nanocrystals with a size of about 5 nm precipitate inside the hair to blacken it (Walter et al. 2006).

Besides all these manufactured products, natural and nonintentional nanomaterials have been also used since antiquity. For instance, asbestos is a group of naturally occurring mineral nanofibers (~ 10 nm in diameter) that represent the most multifunctional nanomaterial in history, with many products and applications since about 1000 BCE because of its range of useful properties. Clay minerals are good examples of the use of natural nanomaterials since ancient times, for medicinal and cosmetic treatments, bleaching of wool and clothes, and so on. Carbonaceous combustion

soot and black carbon are among the ancient and persistent nanoparticulates, used as pigment or as a component of inks. TEM analysis revealed that “Kaajal” (the traditional Indian black cosmetic) contained carbon nanoparticles of different sizes ranging from 2–3 nm and 35–45 nm (Mandal et al. 2013). Silver (in colloidal form) was used as a water disinfectant in classic Greece because of its antibacterial and antifungal properties.

Neutron Activation Analysis (NAA)

THEODORA VASILOPOULOU

Institute of Nuclear and Radiological Sciences,
Technology, Energy and Safety, National Center for
Scientific Research "Demokritos," Greece

Neutron activation analysis (NAA) is a non-destructive, multi-element nuclear analytical technique with excellent sensitivity, great accuracy, and precision that has been successfully used in archaeological and heritage studies since the 1960s (Speakman and Glascock 2007). NAA is based on the detection of the radiation emitted from materials that have previously been irradiated with neutrons. The nuclear reactions carried out in the sample material lead to production of radio-isotopes that emit characteristic gamma-rays (see ISOTOPES; NEUTRON RESONANCE ANALYSIS (NRA); and NON-STABLE ISOTOPES IN ARCHAEOLOGY). The analysis of the acquired gamma-ray energy spectra enables the qualitative and quantitative determination of the elemental composition of the sample under investigation. In order to identify—through the radioactive nuclei produced—the corresponding target nuclei and, hence, the elements composing the sample material, detailed knowledge of the occurring nuclear reactions and reaction rates is required. An important parameter in the activation process is the energy spectrum of the neutrons incident on the sample, which determines the type of nuclear reaction as well as the probability of its realization, and consequently defines the resulting radioactive products. Absolute, comparative, internal monostandard, and k_0 techniques have been developed to quantify the elemental analysis results (Greenberg, Bode, and De Nadai Fernandes 2011).

A nuclear reaction which is often used in NAA is the neutron capture (n, γ) reaction followed by emission of gamma-rays. The interaction of neutron with the target nucleus results in its capture and the production of a compound excited

nucleus. During the decay of the compound nucleus one or more characteristic gamma-rays, known as "prompt" gamma-rays, are emitted. The decay of the compound nucleus may lead to the formation of a radioactive nucleus which thereafter decays, also emitting characteristic gamma-rays. These gamma-rays are called "delayed" so as to be distinguished from the "prompt" gamma-rays. Depending on the type of gamma-rays detected, NAA is classified either as prompt gamma-ray neutron activation analysis (PGNAA), in which sample irradiation and measurements are performed simultaneously, or delayed gamma-ray neutron activation analysis (DGNAA), where gamma-ray measurements start after the end of irradiation. A method for optimization of the detection limit of specific elements (usually forming short-lived radionuclides) is the irradiation and measurement of a sample repeatedly for a short period of time and summation of the gamma-ray spectra from individual runs. This technique is called cyclic neutron activation analysis (CNAA). The need for sample preparation or special treatment during the analysis procedure is another criterion used to assort NAA. According to this classification, the technique is termed instrumental neutron activation analysis (INAA) when no sample treatment is involved and radiochemical neutron activation analysis (RNAA) when the irradiated sample is subjected to chemical separation in order to remove interfering species or to concentrate the radioisotope of interest.

NAA experiments have been performed utilizing thermal, epithermal, and fast neutrons obtained from all available types of neutron sources (nuclear reactors, accelerators, isotopic sources). Nevertheless, the optimum measurement sensitivity is achieved in fission reactors due to the significantly higher neutron fluence rates produced in these facilities.

NAA has important features outbalancing other analytical techniques. First, it is versatile and can be applied on solids, liquids, suspensions, slurries, and gases. It requires almost no sample preparation, eliminating the possibility of

sample contamination in the laboratory, while it is nondestructive, allowing reusing the sample in several experiments. Moreover, it is a time-saving technique enabling the simultaneous determination of several (major, minor, and trace) elements in the same sample. Since the half-lives of different radioisotopes differ, measurement can be delayed to allow interfering species to decay and, thus, eliminate interferences and achieve lower detection limits. NAA provides excellent sensitivity, great accuracy, and precision. Depending on the material under investigation, the sensitivity of the technique may be of the order of parts per billion (ppb). According to Pollard and Heron (1996), accuracy of NAA is in the region of 5 percent and relative precision is often better than 0.1 percent. It has great linearity, which can reach up to 12 orders of magnitude for certain elements; hence, a wide range of elements and concentrations can be detected at the same time. Furthermore, it can be widely applied, since approximately 70 percent of the elements of the periodic table have properties that allow their detection using NAA; namely they are stable isotopes that can be activated if irradiated with neutrons. Because of its great advantages, NAA has been established as an important analytical tool for chemical characterization studies and is often considered to be the reference technique as compared to other analytical methods. The simplicity of the procedure, the fact that little or no sample consumption occurs during the analytical process, and its excellent sensitivity are great benefits that distinguish NAA from similar techniques.

NAA has found a broad range of applications in several fields of science and technology, including archaeology, archaeometry, and heritage studies. Since the 1960s, NAA has been used to analyze archaeological findings or verify the authenticity of important historical objects, distinguishing fraudulent from real artifacts. Moreover, NAA is commonly recognized as the method of choice for archaeological provenance investigations (Speakman and Glascock 2007). Within the context of such studies, the elemental composition profile derived by the analysis of the “unknown” archaeological object is compared against known profiles of already identified raw materials, aiming to find a correlation that will

indicate its exact place of origin. Among the successful applications of the technique one can find chemical characterizations of potsherds, obsidian implements (see *CHERT, SILEX, AND OBSIDIAN SOURCING*), silver and gold coins, glass (see *GLASS AND FAIENCE*), metals (see *CHARACTERIZATION OF METALS AND ALLOYS*), and pigments from paintings and other valuable artworks (see *CHARACTERIZATION OF PIGMENTS*).

In conventional NAA, however, the mass of analyzed samples is in the range of milligrams to grams (or of a few microliters to milliliters in volume), representing only a small portion of the bulk material. This limitation proves to be an important issue that inevitably restricts the potential of the technique. In authenticity and provenance studies, for example, the analyzed archaeological objects are usually precious, non-replaceable artifacts that need to be preserved intact and cannot be damaged for sampling purposes. Furthermore, in the case of heterogeneous materials, which are often met in archaeological and heritage studies, representative sampling is usually a very difficult or even impossible task. In order to fulfill the demand for a nondestructive method capable of analyzing larger material volumes and whole objects, the method of large sample neutron activation analysis (LSNAA) was developed.

In LSNAA, the nondestructive, multi-element character of the conventional NAA technique is combined with the ability to analyze bulk objects, up to several liters in volume, as a whole. Based on the fact that the mean free path of neutrons and gamma-rays within materials is in the order of several centimeters, that is, neutrons and gamma-rays can penetrate deeply into bulk objects, LSNAA enables the nondestructive analysis of voluminous samples, overcoming the obstacle of limited analyzed mass.

The basic principles of LSNAA are the same as those of NAA. The large sample is irradiated in a neutron field and is subsequently transferred to a suitable gamma-ray spectrometry facility to be counted either as a whole or using segmented scanning. The gamma-rays emitted from the activated material are identified and the activity induced in the sample volume is quantified. Finally, the spectra analysis results are interpreted in terms of elemental concentrations. The only parameter that strongly differentiates LSNAA

from the “traditional” technique is the large volume of the studied sample. To account for the voluminous character, a number of corrections need to be applied to the experimental data. These corrections are mainly related to the interaction of neutrons and photons within the sample material, as well as the inhomogeneity and asymmetry of the bulk object. In particular, corrections are required for neutron self-shielding during sample irradiation, gamma-ray self-attenuation during gamma-counting, volume distribution of activity within the large sample material, irregular sample shape, and material inhomogeneity effects. Different methods and algorithms have been proposed for the correction and quantification of LSNA results (Bode 2008).

The development of LSNA increased the potential of the activation analysis method, unfolding new possibilities. As in NAA, the feature of multi-element compositional analysis is coupled with the excellent sensitivity, great accuracy, and precision achieved. In addition, neither chemical nor any other sample preparation is needed. In LSNA, however, the advantages of the conventional technique are significantly extended due to the unique capability of nondestructive bulk material analysis. Since whole-object analysis is performed and no subsampling is required, precious artifacts and historical pieces can be studied without any concerns about their integrity. Apart from the obvious value of preserving the integrity of a precious archaeological finding, the measurement procedure can be repeated whenever it is needed. Moreover, it minimizes—if not totally obliterates—the risks of contamination (e.g., due to drill-bit) during the sampling procedure. Besides, the elimination of the need for subsampling is extremely important in the case of inhomogeneous materials, which cannot be cut into pieces, grinded, pulverized, or in any other way homogenized in order to be analyzed. Another important aspect is that LSNA can be applied using facilities with relatively low neutron fluxes (in the order of 10^6 – 10^9 cm⁻² s⁻¹). Given the fact that the “loss” in the neutron flux is compensated by the greater mass of the analyzed material, low neutron fluxes are adequate for analysis, so a wide range of neutron sources can be used for LSNA experiments: small and medium power reactors, reactor thermal neutron

columns, as well as isotopic neutron sources and neutron generators. At the same time, irradiation in a neutron field with fluxes lower than those used in the conventional small sample analysis (i.e., of the order of 10^7 cm⁻² s⁻¹ for LSNA instead of 10^{13} cm⁻² s⁻¹ for NAA, respectively) implies lower residual specific activity induced in the studied sample. Therefore, shortly after the completion of the irradiation, the sample can be released from regulatory control without any further concerns on the activity levels. In the case of pottery samples, in particular, their low activation properties as compared to other materials (e.g., metals) make the technique ideal for characterization of ceramics (see CHARACTERIZATION OF CERAMICS).

Several analytical techniques have been used in archaeological and heritage research. X-ray fluorescence (XRF) (see X-RAY FLUORESCENCE SPECTROMETRY (XRF)), particle-induced X-ray emission (PIXE) (see ION BEAM ANALYSIS (PIXE/RBS)), atomic absorption spectroscopy (AAS), ion beam analysis (IBA), inductively coupled plasma spectroscopy (ICP) (see ICP-MS AND MATERIAL ANALYSIS), scanning electron microscopy (SEM), radiocarbon dating (see RADIOCARBON CALIBRATION AND AGE ESTIMATION), thermoluminescence (see THERMOLUMINESCENCE), and optical methods (see OPTICAL MICROSCOPY) have been applied, among others, for provenance studies, authenticity verification, dating, and restoration of artifacts. Of course, not all techniques are applicable in each sample case. The selection of the appropriate method depends on the type of the studied material as well as on the objective of the analysis. For example, if the aim of the study is to trace a pottery artifact to its source, namely to determine its elemental fingerprint, then a technique able to provide information on trace elements (such as XRF or NAA) should be employed. Nevertheless, due to its various advantages and, in particular, due to its ability to analyze whole objects, LSNA has proven to be a unique analytical tool, which seems to outweigh other established nondestructive methods, at least in certain cases and applications. For instance, techniques such as IBA, XRF, and PIXE can only analyze superficial layers of the sample material and thus provide limited information on its elemental composition in depth. So, they cannot be used for the analysis

of voluminous or inhomogeneous materials, where the surface profiling is not sufficient. In addition, LSNA results are not affected by post-depositional elemental alterations caused on the sample surface due to, for example, oxidation or sediment deposition, since the analytical information is provided from the total volume of the bulk material and not only from its surface layers. This is a significant aspect, especially in cases of archaeological findings that have been either buried in the earth or sunken in the ocean for a prolonged period, resulting in erosion or distortion of their surface (Schwedt, Mommsen, and Zacharias 2004).

Recognizing the great potential of the technique in the fields of archaeology and heritage studies, archaeologists, art historians, conservators, and museum curators have used LSNA in diverse material investigations. The technique has been successfully applied for the analysis of stone samples, entire potsherds of archaeological interest, irregular-shaped bulk historical objects, and artifacts (Dasari et al. 2010; Bedregal et al. 2014; Vasilopoulou et al. 2015). It has been also used in provenance studies of traditional pottery and in authentication studies of ancient porcelain ware (Zhu et al. 2013).

Further efforts and studies could include—without being limited to—the development of LSNA facilities based on isotopic neutron sources (e.g., ^{252}Cf , Am-Be) or neutron generators, allowing the application of the technique even in cases where a nuclear reactor is not readily available. Such an approach would also facilitate the implementation of in-situ analyses of voluminous objects that cannot be transferred to the laboratory, such as pillars, murals, frescoes, mosaics, and other parts of historical buildings or archaeological sites. Portable LSNA would be a valuable field tool for the in-depth study of various materials, complementing the information that portable X-ray fluorescence spectroscopy (pXRF) (see PORTABLE X-RAY FLUORESCENCE SPECTROMETRY (PXRF)) provides. Another aspect that is worth being investigated is the use of NAA as a screening method for inhomogeneous bulk materials and objects. For instance, the development of neutron imaging and tomography is of great importance in authentication and conservation studies (see NEUTRON IMAGING AND TOMOGRAPHY IN CONSERVATION).

The combination of computed tomography or neutron radiography techniques (see NEUTRON RADIOGRAPHY AND TOMOGRAPHY) with focused neutron beams and prompt gamma-ray analysis may lead to new and innovative applications.

Neutron Diffraction (ND)

WINFRIED KOCKELMANN

STFC Rutherford Appleton Laboratory, UK

EVELYNE GODFREY

Uffington Heritage Watch Ltd, UK

Neutron diffraction can determine the bulk microstructure of archaeological materials by completely noninvasive means, in terms of the mineral and metallic constituents. Neutron diffraction is consistent with the ethical considerations of conservation science (see CONSERVATION SCIENCE). Assemblages of intact artifacts can be analyzed with no need to remove samples; the object is unaltered by the neutron beam, and no special sample preparation or environment is required. A far greater number of objects can be analyzed than would ever be possible by metallographic techniques (see METALLOGRAPHY), as curators rarely allow destructive sampling for optical microscopy. The aim of the crystallographic characterization is to reconstruct technical details of fabrication methods in early metalworking, such as alloying, casting, hammering, and heat-treatment. The main advantage of neutron diffraction compared to X-ray diffraction in archaeometallurgy is the high penetration property of a neutron beam. The method measures right through the thickness of an object, giving average quantitative structure data from internal parts (Kockelmann, Kirfel, and Haehnel 2001; Kockelmann et al. 2006). Emerging Bragg-edge transmission analysis techniques provide new opportunities for structure studies of archaeological materials in a radiography-type setup. Neutron diffraction analyses are performed at “large-scale” facilities such as nuclear reactor sources and accelerator-based neutron spallation sources.

The information from neutron diffraction is used in conjunction with other nondestructive methods. X-ray radiography (see X-RAY RADIOGRAPHY), neutron radiography (see NEUTRON

RADIOGRAPHY AND TOMOGRAPHY), and X-ray tomography (see X-RAY TOMOGRAPHY) are used to assess the preservation state of an object and to help find the analysis points for neutron diffraction. Neutron diffraction can also be useful in selecting points for metallographic sampling if, for example, a large assemblage of objects is being examined, but destructive sampling can only be carried out on a very limited proportion. Spatially resolved elemental data can be acquired from objects using complementary noninvasive neutron-based techniques such as prompt gamma activation analysis and neutron resonance capture analysis (see NEUTRON RESONANCE ANALYSIS (NRA)). Multiple data points can be collected by neutron diffraction, overcoming the interpretive problem of relying on just one or two very small metallography sections in order to characterize a whole—typically heterogeneous—ancient artifact.

High-intensity beams of thermal and cold neutrons are produced in nuclear reactions, in either nuclear reactors or accelerator-based spallation neutron sources. Neutrons have no charge, are able to penetrate deep into a material, and hence come close to nuclei unimpeded by the electrical Coulomb forces, and interact with the nuclei via the strong force. The interactions are weak, and thus, when neutrons hit a solid, most of them pass through it and only a small fraction is scattered. Neutrons are therefore able to penetrate bulky or thick samples that can be several centimeters in diameter. Neutrons have a spin and magnetic moment, and hence interact with unpaired magnetic moments of the electron shells of atoms.

Neutron diffraction is a phase- and structure-sensitive method. Diffraction (see DIFFRACTION) is described by Bragg's law which treats the scattering process as reflection by crystal planes. The primary difference between X-ray and neutron diffraction lies in the form factor, which for neutrons is termed “scattering length” and describes the interaction between neutron and nucleus. For most isotopes the scattering length adopts a fixed value, that is, it does not depend on the energy

and scattering angle of the diffracted neutrons, in contrast to the form factor for X-ray diffraction. The neutron scattering length varies in an almost random manner with atomic number in the periodic table of elements. By comparison, for X-rays the atomic form factor is related to the number of electrons in orbitals surrounding the nucleus. Consequently, in the presence of heavy atoms, light atoms such as hydrogen and oxygen have small scattering powers for X-rays, but have good visibility in neutron scattering. The magnetic interaction of neutrons with long-range ordered structures of magnetic moments gives rise to magnetic diffraction peaks which can be used to identify and study ferromagnetic, ferrimagnetic, and antiferromagnetic structures of, for instance, ferritic iron, magnetite, and hematite.

The common neutron diffraction methods in archaeological science are derived from well-known X-ray or neutron powder diffraction approaches. Polycrystalline archaeological materials will contain one or more crystalline phases, with distinct crystal structures and compositions according to their locations in phase diagrams. As with other diffraction methods,

neutron diffraction can disentangle, quantify, and characterize phases in polycrystalline mixtures if present in sufficient amounts. Neutrons penetrate inorganic objects better than X-rays, for instance, allowing measurement of thick lead or leaded-bronze objects. Neutron analysis can determine how much metal is preserved under thick corrosion layers. The bulk composition and the microstructure of the metal is determined independent of the corrosion phases, as these are detected as distinct signals.

Neutron diffraction does not require material to be removed from the object. The method uses a large beam that illuminates the whole object, or part of the object. The incident neutron beam is collimated to cross-sections of a few square millimeters or centimeters, in analogy with what is routinely carried out to measure residual strains via neutron diffraction (Figure 1a). The sample or an entire object is usually placed in air on a remote-controllable laboratory table without any sample preparation. Sample positioning tables on neutron diffractometers may accommodate 1-m-large objects. The part of the object to be studied is aligned in the neutron beam

Figure 1 Analytical setup for neutron diffraction. (a) Schematic of a diffractometer at a pulsed neutron source with diffraction detectors at 90 degrees. (b) An Early Medieval iron sword mounted for neutron analysis by the conservation scientist.

(Figure 1b). Analysis points are selected based on visual features on the surface of the object, on X-ray radiographies, neutron radiographies or tomographies, or 3D laser scans of the external surface. Neutrons penetrate into the interior of the object; most neutrons pass through without interaction and are collected in a neutron camera or are removed by a “beamstop.” Part of the neutron beam is scattered in the sample, and part of those neutrons are registered in neutron diffraction detectors that are typically at a distance of 1–2 m from the sample. By collimating both the incident and diffracted beams, only neutrons are recorded that enter and emanate from a certain “gauge volume” inside the sample (Figure 1a). The minimum gauge volume for neutron diffraction is in the order of 1 mm³. By scanning the laboratory table, different parts of the sample can be interrogated and point-by-point structure maps can be obtained. It takes typically a few minutes up to several hours to collect a data point, depending on the neutron source strength, the gauge volume size, the detection efficiency, and the interaction cross-sections of the material. Multiple points can be collected across an object to produce a linear scan, or a 2D or 3D structure map.

The angle-dispersive neutron diffractometer uses a monochromatic beam, analogous to the Debye-Scherrer geometry in X-ray diffraction; diffracted neutrons are registered as a function of the scattering angle. The energy-dispersive neutron diffractometer uses a polychromatic beam, and diffracted neutrons are registered as a function of neutron energy or neutron wavelength. In either case, diffraction patterns are often displayed as counts versus crystallographic d-spacing (Figure 2) by making use of Bragg’s law.

Neutron diffraction at a pulsed spallation source has many advantages, such as ease of sample positioning and short data collection times. Data are collected in a combined angle- and energy-dispersive mode with time-resolving detectors at given scattering angles. Energy-discrimination is straightforwardly achieved by time-of-flight (ToF) measurements. With a given flight path and measured arrival time of a neutron in the detector, the velocity of the neutron and, via deBroglie’s relation, the wavelength can be determined. The sample is irradiated with polychromatic bunches of

Figure 2 Neutron diffraction patterns from 2×2×2 mm² volumes of an Early Medieval iron sword. Some of the strong Bragg peaks are labeled. (a) Rietveld analyzed pattern from the back of the sword of internal volume underneath the corrosion layers, exhibiting ferrite, cementite, and magnetite. (b) Diffraction pattern from the edge of the sword, exhibiting magnetite and goethite phases in addition to ferrite.

neutrons which are registered in multidetector arrays comprised of hundreds and thousands of individual elements, each of them yielding a ToF diffraction pattern. This is a particularly useful feature for archaeological studies where a detector at a convenient scattering angle can be chosen. This also means that the data collection can be performed on stationary objects, or with minimal sample movements. The patterns from different detector elements are normally summed up to increase counting statistics and to simplify the data analysis. For certain applications, as is the case for texture studies, the diffraction patterns from different detectors are analyzed separately.

An important parameter of a neutron diffractometer is its resolution, describing the instrumental contribution to the Bragg peak widths. It depends on, among other things, the

chosen wavelength and the scattering angle. On a neutron diffractometer, the best resolution is achieved at high scattering angles, yielding the sharpest diffraction peaks, where sample-related peak broadening effects are recognized first. A good instrument resolution is required for peak separation in multi-phase sample patterns, for line-width analyses, and for accurate determination of lattice parameters.

A neutron diffraction pattern contains a series of Bragg reflections. The positions, widths, and intensities of Bragg peaks of a phase are analyzed, much like X-ray diffraction patterns, in terms of unit cell dimensions, crystal structure, microstructure, and preferred orientation of crystallites. Quantitative analysis can be performed by Rietveld refinement (Figure 2). The Rietveld profile refinement technique (Rietveld 1969) is an established method for quantitative phase and structure analysis in X-ray and neutron powder diffractometry. Rietveld analysis is performed by least-squares fitting calculated diffraction patterns against observed diffraction patterns, as shown in Figure 2, based on a structure model made up of the different phases in the sample. A full-pattern and multi-pattern Rietveld fitting approach is used to quantify the phase compositions, structure parameters, microstructure parameters, and crystallographic texture. The appeal of Rietveld methods for analysis of archaeological materials lies in its robustness with neutron data. Also, no internal standard is required for evaluation of relative phase fractions.

Neutron diffraction provides a structural characterization of crystalline phases, allowing description of metallurgical manufacturing techniques and evaluation of the state of preservation. Each corrosion compound forms a separate mineral phase, which can be distinguished and quantified from the diffraction pattern. The volume of preserved metal that is present underneath the corrosion layers can be calculated. Neutron diffraction finds phase abundances down to a typical normalized fraction of around 0.1 wt%.

Sometimes it is possible to calculate chemical (element) concentrations, by quantifying atomic compositions of discrete phases. For example, as lead does not form a solid-solution with copper, neutron diffraction can determine lead contents by quantifying the segregated metallic phase in a copper alloy object. In steel, for instance,

carbon is present as an intermetallic compound, cementite, containing 6.7 wt% carbon. Neutron diffraction measures the cementite phase in a volume of steel, which is then translated into the bulk chemical composition of weight percent carbon. Furthermore, binary alloy compositions can be derived by accurate lattice parameter determination, by Rietveld refinement of the unit cell expansion due to incorporation of the alloying element (e.g., Sn in Cu; C in Fe; P in Fe; Cu in Au or Ag) (Siano et al. 2006).

Residual strains and microstrains in metal objects are determined, for instance to reveal cold-working of a copper alloy artifact. Structural defects such as atom vacancies, presence of inclusions, and lattice defects may be responsible for local distortions and lattice deformations. Defects, microstrains, and residual strains are induced by mechanical, thermal, and chemical processing conditions, while slow heating and annealing may reduce crystal defects and relax lattice strains. Diffraction and ensuing reflection line profile analysis provide indications of such working processes, particularly useful if microstructural trends are revealed by comparison with suitable reference samples that are produced in a controlled way. Quenching and tempering of steel can be detected, as these treatments produce distinctive changes in the neutron diffraction pattern with regards to Bragg peak shifts and Bragg peak broadening.

The mutual orientations of grains can be analyzed by crystallographic texture analysis on a neutron diffractometer. Neutron texture analysis determines the orientations of crystallites in a statistical sense for the interrogated gauge volume inside an object. If the grains are oriented at random and if all grain orientations are equally realized then the material is said to be free of texture. Texture is an important material characteristic of metals and ceramics. Since texture is usually a result of solidification and manufacturing, it can contain information about the production history of an object. The method allows evaluation of the orientation distribution function (ODF) based on the measurements and analysis of a multitude of diffraction patterns collected at different scattering angles. The texture manifests itself as intensity variations of Bragg peaks as a function of scattering angle. Neutron texture analysis permits fast analysis of the ODF

for a single analysis point in several minutes. With respect to conventional metallography, the texture information seen by neutron diffraction is complementary and highly significant from the point of view of grain statistics because of the large number of crystals contributing to the diffraction signal and from the point of view of three-dimensional (3D) sampling of an object. Quantifying grain orientation distributions by neutron texture analysis is particularly relevant for metals, in order to reconstruct their thermal and working history (Artioli 2007).

Neutron diffraction is not normally applied to glassy and amorphous materials. The method is also inapplicable if spatial information of just a few microns is required. Neutron diffraction methods are limited to millimeter-sized spatial resolution and minor (not trace) phase fraction contents. Although the neutron diffraction beam is relatively large and many cubic centimeters of a material are analyzed, it is of low intensity, so that long measurement times are needed compared to X-ray diffraction analyses.

Small angle neutron scattering (SANS) requires a different neutron diffraction setup. SANS is based on elastic neutron scattering of thermal neutrons. Porosity of a material and size and surface characteristics of mineral aggregates can be studied. The method probes larger-scale structures, however, on extracted, typically small samples.

ToF neutron imaging setups at spallation sources can map structural parameters through analysis of Bragg edges via energy-dispersive neutron radiography. This technique is connected to neutron diffraction via Bragg-edge transmission analysis (Santisteban et al. 2001). It makes use of the fact that the transmission varies because neutrons are removed from the primary beam due to Bragg scattering, producing sharp Bragg-edge features. The method uses a broad neutron wavelength distribution at a pulsed source, with a time-resolving neutron imaging camera behind the object. The Bragg edges are mapped with a spatial resolution in the range of 0.1 mm and analyzed with Rietveld-type approaches in terms of positions, widths, and heights of the edges. These parameters can then be translated into phase, strain, and texture parameters of the material, and neutron radiography and tomography techniques can be employed to obtain 2D and

3D maps. It is anticipated that this emerging method will extend the use of neutron diffraction techniques for archaeological science.

Neutron methods do not mark, heat, or alter the object. There is a short-term activation, but, generally, the activation is low and short-lived. Copper alloy objects, for example, are typically active up to three days after analysis before being cleared for return to the owner, depending on thickness and composition. Iron artifacts are generally not active at all after analysis. Decay of activation is slower for certain elements such as cobalt, silver, gold, manganese in iron, and tin in copper. After around two hours of exposure to neutrons, a manganese-containing object, for instance, might need two to three days before it can be cleared for return.

In summary, neutrons penetrate inorganic objects better than X-rays, for instance allowing analyses of thick lead, leaded-bronze, and iron objects. Neutron diffraction can be used to detect and characterize metal under thick corrosion layers in a nondestructive way, without special sample preparation. The bulk composition, texture, and microstructure of the metal are determined independent of the corrosion, albeit with limited spatial resolution of a few millimeters.

Neutron diffraction is used in the study of archaeological finds and collections research in conjunction with other nondestructive methods such as radiography. The technique provides data complementary to that obtained by conventional analytical methods, such as optical and scanning electron microscopy, and X-ray diffraction of mineral phases. Well-characterized standards that have been produced according to ancient technological practices should be analyzed alongside the archaeological material. A conservator, conservation scientist, or archaeological scientist specializing in the material should be closely involved from the proposal stage through to the practical application of neutron analysis of archaeological objects.

Neutron Radiography and Tomography

EBERHARD H. LEHMANN and DAVID MANNES

Paul Scherrer Institut, Switzerland

Archaeological samples and objects from our heritage are often unique and are highly important for understanding the past. If they are investigated for scientific reasons in order to derive information about composition, age, conservation status, or hidden structures, such investigation should be carried out nondestructively and noninvasively. In this way, the often valuable objects are protected and available for future generations.

There are several methods established for this purpose, which have advantages but also limitations. This entry focuses on neutron imaging techniques, which have progressed a lot in recent years and been made available also for the study of archaeological objects. We compare in some cases these neutron methods with similar studies using X-rays. The X-ray approach is more common and has been in use for many decades (see X-RAY RADIOGRAPHY and X-RAY TOMOGRAPHY).

While neutron imaging techniques can compete in image quality today, the contrast and the information obtained from them is complementary to X-ray data. This is because of the differing interaction mechanisms of each radiation method. The principles of the two methods are described in more detail below.

Both X-rays and neutrons have the ability to transmit radiation through most materials with a probability that depends on the thickness, composition, and interaction rate (macroscopic cross-section) of the materials involved. Because X-rays interact exclusively with electrons in the atomic shell, the attenuation is increased much towards heavier elements. Since neutrons interact only with the atomic nuclei by absorption and scattering in a completely different manner, no dedicated rule for the different isotopes can be formulated. Generally, lower mass materials

(H, B, Li, and so on) can deliver much higher contrast than X-rays can provide, while many heavier materials (Pb, Bi, Pt, W, and so on) are much more transparent for neutron beams (see NEUTRON RESONANCE ANALYSIS (NRA)).

Using these properties of the two kinds of radiation in the right manner, samples can be analyzed easily in the radiography mode, where a shadow image is obtained using a suitable detector device. The example in Figure 1 illustrates the differences in neutron and X-ray transmission, while the inherent image quality is identical. With the X-ray image, the metallic parts are pronounced, while the wooden handle only becomes visible with the neutron image. Both datasets together will deliver the whole picture. A complete three-dimensional structure analysis can be obtained by the tomography approach (see details below).

Neutron beams with suitable intensity and beam quality can only be found at large-scale facilities, either reactor based or with accelerator-driven spallation sources. Thermal and cold neutrons are preferred due to the interaction rates and the options for highly resolved images with best possible image contrast. Such sources are huge installations, a long way from being mobile. Samples have to be transported from the museum and back. Their operation is organized according to a “user laboratory.”

Methodological aspects

Sources and detectors: practical imaging conditions

In order to obtain image data of the quality shown in Figure 1, the beam from the source has to be tuned by collimation. Both X-rays and thermal neutrons cannot be influenced much by optical elements or by magnetic fields. The collimator is used to select and separate the most suitable beam components. In the best case, the beam is parallel and uniform and has an equal spectral distribution. Its size (field-of-view (FOV)) should

Figure 1 X-ray (left) and neutron (right) radiography images of a fifteenth-century sword from Oberwil (Canton Zug, Switzerland), in which the different contrasts for metallic parts and wood are demonstrated.

fit the object's dimensions. Since these conditions are never fulfilled perfectly, some compromises and corrections have to be made.

After passing through the object, the residual beam component is observed by using a two-dimensional detector, optimized for the particular kind of radiation. While X-rays can be detected directly, neutrons have to be converted first into an ionizing kind of radiation by a nuclear reaction, for example, capture in Li-6 or Gd-157 (see NEUTRON RESONANCE ANALYSIS (NRA)). In the past, a specific kind of film was used which had to be developed in a chemical process after exposure. Therefore, the “frame rate” was in the order of two images per hour only. In the meantime, several electronic detection systems have been developed and put into practical use (Mannes et al. 2015). Most common nowadays are systems with a combination of scintillators and highly efficient cameras, optimized for either high spatial resolution (Lehmann et al. 2004), large FOV, or high temporal resolution (Lehmann et al. 2007). Advantages of the digital imaging systems are the options for post-processing and image correction, much lower exposure time (less sample activation in the case of neutrons), flexibility in relation to FOV and resolution, and direct

quantification of the image data, for example, in the tomography reconstruction process.

Tomography: accessing the third dimension

Digital transmission data are structured in pixels as a two-dimensional matrix of gray values. Assuming Beer–Lambert's attenuation law can be applied for the transmission process, the attenuation coefficient Σ can be derived for each pixel, comparing the intensities with (I) and without (I_0) sample, related to the thickness d in beam direction z :

$$\Sigma(x, y) = \ln \left(\frac{I_0(x, y)}{I(x, y)} \right) / d(x, y) \quad (1)$$

Deriving attenuation coefficient values $\Sigma(x, y, z)$ for the third dimension also requires projections of the object from all directions (100 ... 1,000) and a mathematical algorithm for volume retrieval. Such an algorithm is based on the radon transformation of the projection data and a filtered back-projection into the voxel matrix. In the simple case of a parallel beam, the reconstruction with modern tools using advanced computer

Figure 2 (Left) Virtual slices through the lower part of the sword handle: upper row (a, b, c), neutron tomography data; lower row (d, e, f), X-ray tomography data. The wood structure is visible in the neutron data, and metallic parts are pronounced by the X-ray data.

power can be done in a few minutes, depending on the data volume (number of pixels). Since high-resolution detectors provide already 2048 pixels in one direction, the resulting voxel matrix is in the order of 17 GB (gigabytes). This is not a real problem for data storage today but for the visualization steps in the data treatment, because the computer memory has to be in the order of twice the data volume for manipulation and tuning. In the case of a conical beam, the reconstruction algorithm is more demanding, for instance, using the Feldkamp algorithm.

The result of a reconstructed tomography dataset is a stack of tomograms, that is, slice images perpendicular to the rotation axis. This stack of images represents a three-dimensional volume data, which can be virtually sliced in any direction. The results can be presented in different ways. Tomography slice images deliver important information (cf. Figure 2) (Mannes et al. 2015). As shown in Figure 2 with the case of the sword from Oberwil (Figure 1), it is possible to give a perspective view of the tomography data by volume rendering provided by dedicated software tools.

If the three-dimensional material distribution is known, it is also possible to derive the material thickness from the precision of the detector resolution. This has been performed in the case of the famous golden bust dedicated to the Roman emperor Marcus Aurelius found near the former

Figure 3 Wall thickness determination from tomography data of the Marcus Aurelius bust from Avenches. The object is 33.5 cm high, hollow, and contains nearly 1.5 kg of pure gold.

settlement Aventicum (now Avenches, Switzerland). The gold distribution with respect to the wall thickness is color-coded for the whole object in Figure 3. This information gives insight into the manufacturing process in Roman times (de Pury-Gysel, Lehmann, and Giumlia-Mair 2016).

Application to heritage objects

Selection of the most suitable setup for investigations

Requests to study museum objects in either radiography or tomography mode are versatile. It depends on the composition and size of the sample which kind of radiation and which particular methods, facility, detection technique, and observation strategy are applied. In many cases, a combination of methods is preferable (radiography and tomography; neutrons and X-rays; diffraction (see NEUTRON DIFFRACTION (ND)) and imaging (see IMAGING)).

Generally, transmission and contrast limit the chance of a successful study. Based on the tabulated cross-section data Σ for thermal neutrons and μ for X-rays, respectively, the layer thickness for the remaining 2 percent transmission $d_{\max}$ can be estimated in advance of a real experiment (where N is the nuclear density of the involved materials and σ is the microscopic cross-section):

$$d_{\max} = \frac{3.91}{\Sigma} = \frac{3.91}{\sigma \cdot N} \quad (2)$$

The minimum distinguishable material layer for a specific material can be derived in a similar manner when a 2 percent contrast difference is analyzed:

$$d_{\min} = \frac{0.02}{\Sigma} = \frac{0.02}{\sigma \cdot N} \quad (3)$$

There are several tricks and options (e.g., different energies of the radiation) to overcome these limits in some respect, but not by orders of magnitude. As a first guideline, equations 2 and 3 are well applicable.

As well as the transmission and contrast issues, the dimensions of the objects have to fit the beam size and the detector's FOV. Neutron beams up to 40 cm in diameter are available, while the highest resolution of only 5 μm can be achieved with 1 cm^2 FOV. This gives high flexibility to perform different studies.

Advanced neutron imaging methods

Many studies have been performed successfully using radiography and tomography methods. However, neutron beams can also be used in

an advanced manner for specific and dedicated investigations.

In the case of the neutron imaging facilities at the Paul Scherrer Institut, Switzerland, the beam is delivered from the source in a broad spectrum (Maxwellian distribution) either at around the average energy of 25 meV (wavelength 1.8 Å) for thermal neutrons or at an even lower mean energy of about 3 meV for cold neutrons. Most structural materials are microcrystalline with different grain size and orientation (texture). Each crystal structure corresponds to a Bragg scattering feature that is visible as far as the sharp edge given by the scattering conditions according to Bragg's law (see DIFFRACTION).

Energy-selective imaging becomes available when the spectrum is reduced to a narrow band where the crystal orientations can be observed individually. Technically, this band selection is performed by means of turbine-type selectors or double-crystal monochromators with a resolution between 2 and 15 percent in the wavelength. Even higher resolution can be obtained with a time-of-flight approach using pulsed neutron sources. Such methods have been applied successfully to studies on ancient Japanese swords (Salvemini et al. 2012). It is particularly important in the study of ancient welds, to see how they were done—nondestructively.

Diffraction neutron imaging is a technique where an object is investigated not only in the transmission mode but also with simultaneous observation of the diffracted component. These data can be used to provide information about the crystalline structure of the object too; larger crystal zones will deliver brighter spots in the diffraction image. This method is still under development but has great potential for noninvasive material characterization.

Neutron grating interferometry, in particular the use of the “dark-field” signal, has been implemented recently and can be used as a tool for material characterization with respect to inclusions or mixing phenomena in the order of micrometers.

Data fusion between neutron and X-ray images can be done with a second source included in the neutron imaging facility, where images of the object are obtained either simultaneously or sequentially with the same pixel matrix but a different image contrast (Mannes et al. 2015).

The corresponding evaluation procedures are the subject of current development.

Data analysis and image processing

Modern neutron (and X-ray) imaging techniques are based on digital detectors. Therefore, the whole branch of common image processing tools is applicable. However, for full usage of the image information, knowledge is required of how the image is produced, which inherent image distortions and artifacts are induced, and how to correct such effects in the best way possible in order to avoid quality reductions. This is particularly important in the application of very old samples, where often no template, copy, or pre-description are available. These unique objects have to be analyzed carefully both qualitatively and quantitatively.

Tools and procedures

Digital data from the transmission measurements should be in a format with a wide dynamic range (at least 16 bits), with a linear response to the attenuated signal, and readable by standard tools (ImageJ, IrfanView). Today, such freeware tools are available to and useful for normal users with experimental beamlines. As well as this approach, programs like IDL and Matlab are useful for large series of data treated under identical conditions. Some programming in different languages (C++, Java, and so on) is required in special cases where standard tools are not flexible or powerful enough. In the case of tomography reconstruction and visualization, useful tools have been built, but mostly are only commercially available.

Limits in quantification

The transmission data from the imaging process can be used for the quantification of the sample's content in the first order only. Using Beer–Lambert's law in equation (1), the image data $I(x, y)$ can be related to the “open beam” data $I_0(x, y)$, and by knowing the sample thickness, the content information can be derived. However, due to scattering effects which induce directional

and spectral changes of the transmitted component, a deviation of the conditions assumed in equation (1) can happen. It depends on the importance of the scattered part of the beam how much the quantification process is disturbed. There are several approaches to overcome the situation using correction tools or special experimental procedures (Hassanein, Lehmann, and Vontobel 2005).

Data handling and archiving

As it becomes more and more common to perform digital imaging using either X-rays or neutrons for museum objects, the data storage, exchange format, and final archiving are highly important. The data volume, driven by the higher pixel density of the sensors, is in the megabyte range for simple radiography, but reaches gigabytes to terabytes in the case of tomography and time sequences. It will be an important work in itself to define the most suitable data formats (without loss of information) and long-term available storage devices for all data obtained today and in the near future. Some pioneering work is being done in the framework of national and European projects.

Conclusion

In summary, neutron and X-ray imaging methods are valuable tools for noninvasive studies of museum objects and archaeological and paleontological samples. While X-ray facilities are available at many laboratories, neutron beam lines are linked to a limited number of large-scale facilities. In the case of the Paul Scherrer Institut, both methods are combined in one facility. Access to the large-scale facilities is in most cases organized via a proposal procedure, where research applications are ranked and beam time is delivered accordingly.

The outcomes of neutron (and X-ray) studies are images in 2D and 3D with the specific contrast of the applied radiation. Experts in archaeometry and cultural research need to learn how to evaluate and interpret the data, including the extraction of numerical information.

Neutron Resonance Analysis (NRA)

P. SCHILLEBEECKX

European Commission Joint Research Centre, Geel, Belgium

H. POSTMA

Reactor Institute Delft, Netherlands

Neutron resonance analysis (NRA) is very suitable for obtaining bulk elemental compositions of archaeological objects. It is based on two methods: one (NRCA) on capture spectrums and the other (NRTA) on transmission through the object.

Neutrons can lead to various kinds of reactions when they interact with nuclei. Since the neutron is an electrically neutral particle, it can enter the nucleus easily, forming a new, highly excited (compound) nucleus of the same element but with an additional neutron. The compound nucleus can either re-emit a neutron, which is effectively a scattering process, or it can emit prompt gamma-rays (γ -rays), or in the case of some heavy nuclides, it can induce fission. The latter is not of interest for the current discussion. The strength of these reactions as a function of neutron energy shows peaks. They are related to excited states of the compound nucleus and are known as “resonances”.

Resonances occur at energies that are specific for each nuclide and can be considered as “fingerprints” of elements and/or isotopes. Thus, elements can be identified on the basis of resonance energies in a neutron spectrum, while areas of resonance peaks provide information about the elemental (or isotopic) composition. It is clear that this way of detecting elements requires a source of neutrons over a wide energy range.

To determine the energy of a neutron that interacts with a nucleus, the *time-of-flight* (TOF) technique is a convenient method. With this technique the neutron velocity ($v = L/t$) is determined from the time (t) a neutron needs to

travel the distance (L) from the neutron source to the object positioned in the neutron beam. For non-relativistic applications, the neutron energy is given by $E = \frac{1}{2}mv^2$ with m being the neutron mass.

For timing the neutron, a start pulse from the neutron source and a stop pulse from the detection of the neutron is needed. This requires a pulsed neutron source. For instance, the neutron source of the GELINA facility operated by the Joint Research Institute of the European Commission (EC-JRC) in Geel (Belgium) can be used for such experiments. A pulsed electron beam is accelerated to a maximum energy of about 140 MeV and impinges on a uranium target. The resulting “Bremsstrahlung” produces neutrons mainly by photonuclear reaction. Another important kind of a pulsed neutron source is located at the ISIS facility of the Rutherford-Appleton Laboratory in Harwell, UK. This source is based on spallation of nuclei by high-energy protons. More about the TOF technique can be found in Schillebeeckx et al. (2012).

Observation of resonances as a function of neutron energy leads to neutron resonance analysis (NRA), for which two detection methods can be applied. In one method, the prompt γ -rays emitted after neutron capture are detected. This is referred to as *neutron resonance capture analysis* (NRCA). This method requires γ -ray detectors with a good time resolution, which are positioned near the artifact in the neutron beam. Neutron resonances are also visible in a neutron spectrum measured after the transmission of a neutron beam through a sample, again as a function of neutron energy. This requires a neutron detector placed at a distance behind the sample. Neutron transmission spectrums show dips at certain resonance energies, on which the *neutron resonance transmission analysis* (NRTA) method is based.

Related analyzing methods are neutron activation analysis (NAA) based on the remaining activity after neutron capture (see NEUTRON ACTIVATION ANALYSIS (NAA)), and prompt gamma-ray analysis (PGA) based on the detection of prompt γ -rays of specific energy.

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0408

NAA and PGA require intense (sub)thermal neutron beams interacting with the objects. For NAA, activation of the object is an essential part of the method. In the case of PGA, it is an unwanted aspect. With NRCA, activation is low due to a high detection efficiency, while activation is further reduced by removing low-energy neutrons with a high activation probability, by using suitable filters.

Neutron cross-sections

The probability of a nuclear reaction is expressed as an effective area known as the cross-section, and denoted by σ . The standard unit for measuring a nuclear cross-section is the barn, with $1 \text{ b} = 10^{-28} \text{ m}^2$. Resonance structured cross-sections can be parameterized in terms of resonance parameters. For an isolated single resonance it is the sum of a pure resonance part, a contribution due to potential scattering, and an interference term between resonance and potential scattering. The contribution due to scattering from the nuclear potential is a smooth function of energy. In the low-energy region it can be approximated by $\sigma_{\text{pot}} = 4\pi R'^2$ in which R' is the effective nuclear radius. Normally, potential scattering is small compared with resonance scattering, and the influence on the shape of total resonance cross-section (scattering plus capture) is often negligible. In the Single Level Breit Wigner (SLBW) approximation, the resonance part of the total cross-section in the region of a single neutron resonance is of the form $\sigma_0/(1+x^2)$, in which $x = 2(E - E_\mu)/\Gamma$, E_μ is the central energy of the resonance, Γ is its width at half-height, and σ_0 is the maximum value of the resonance part. The total width is the sum of the partial widths of all open reaction channels. In case only neutron capture and elastic scattering are possible, the total width is $\Gamma = \Gamma_n + \Gamma_\gamma$. The partial neutron (Γ_n) and gamma widths (Γ_γ) are related to the relative probability that an elastic scattering and capture reaction, respectively, occurs. The neutron width is also a measure of the probability of forming the compound nucleus. The capture cross-section in SLBW in the region of a single resonance is the resonance term of the total resonance cross-section multiplied by the fraction Γ_γ/Γ .

For most of the elements, cross-sections show a large number of resonances in the energy region below 10^4 eV . Exceptions are those of the lightest elements and elements with both the proton and neutron numbers close to the so-called “magic numbers”. Neutron resonance analysis (NRA) can therefore be carried out for a large number of elements (isotopes) in the neutron energy range between 1 eV and 10^4 eV .

The observed neutron resonance profiles are modified compared with the SLBW expression. This is due to several effects, namely:

1. Broadening by thermal motion. This requires a convolution with the thermal distribution function, which leads to the *Doppler broadened cross-section* $\sigma_\gamma^D(E)$.
2. The finite time resolution of the TOF spectrometer.
3. In the case of NRCA, reduction of the beam intensity. In the region of strong resonances, this effect, known as resonance self-shielding, will result in a large reduction in the intensity.
4. In the case of NRCA, neutron scattering (once, twice, or even more) inside the object before capture. Since the energy lost by neutrons during scattering depends on the scattering angle, broad structures may arise on the high-energy sides of resonances due to such multiple interaction events.

The original resonance has a Lorentz shape, while for most applications the thermal distribution function is Gaussian-shaped. As a consequence the Doppler broadened cross-section can be approximated by a Gaussian shape around the central energy and a Lorentzian shape at the wings.

Neutron resonance capture analysis (NRCA)

The main parameter of interest for NRCA application is the integrated area (A_γ) of the capture resonance peak. The integrated resonance area (A_γ) in the case of a neutron capture reaction, expressed in barn.eV, is:

$$A_\gamma = 4.097 \times 10^6 ((M + m)/M)^2 g_I \Gamma_n \Gamma_\gamma / E_\mu \Gamma \quad (1)$$

where m is the mass of the neutron, M is the atomic mass of the interacting nucleus, and the term g_f is related to the coupling of the particle spins. The resonance energy E_μ and resonance widths ($\Gamma_n, \Gamma_\gamma, \Gamma$) are expressed in eV. While Doppler broadening lowers and widens a resonance, it does not change the resonance area.

The number of integrated capture counts N_μ observed in a resonance μ at energy E_μ in a homogeneous and flat object is given by (Postma and Schillebeeckx 2010):

$$N_\mu = \varepsilon_\mu F_\mu A_{\gamma,\mu} a_\mu n_x \Omega \Phi(E_\mu) \quad (2)$$

Here ε_μ is the detection efficiency for the prompt γ -ray at this particular resonance, F_μ is the self-shielding factor integrated over the resonance, $A_{\gamma,\mu}$ is the area of the capture resonance, a_μ the isotopic abundance, Ω the area of the sample illuminated by the beam, $\Phi(E_\mu)$ the time-integrated neutron flux at the resonance, and n_x the total number of nuclei per unit area of element X. Multiplying n_x with the atomic mass of element X gives the amount of weight (W_X) observed in the part of the object illuminated by the beam.

To extract the number of nuclei from the number of counts, all the other quantities in the expression for N_μ need to be known. Unfortunately, the detection efficiency ε_μ , solid angle Ω and absolute neutron flux are very difficult to determine accurately. A direct use of the relationship also requires knowledge of the resonance areas, which is not always available. In addition, archaeological artifacts mostly have a complex shape, which requires integration of the above expression over the illuminated part of the object, making absolute corrections for self-shielding and multiple interactions difficult. Therefore, a more empirical approach is mostly applied. Applying this approach, referred to as the *double ratio method*, several of the parameters cancel. The ratio of the weights W_X and W_Y of the elements X and Y in an object is obtained from the ratio of counts N_X and N_Y , by comparing with the same ratios of a known calibration sample:

$$\frac{W_X}{W_Y} = K_{\mu,\lambda}^{cal} \frac{F_\lambda N_\mu}{F_\mu N_\lambda}, \text{ with } K_{\mu,\lambda}^{cal} = \left(\frac{F_\mu N_\lambda W_X}{F_\lambda N_\mu W_Y} \right)_{cal} \quad (3)$$

The calibration factor $K_{\mu,\lambda}^{cal}$ can be obtained from measurements of calibration samples with a known composition and thickness. The self-shielding factors, denoted by F , can be calculated with the aid of known total cross-sections. Often for each element, several resonances with different strengths can be observed. This leads to the possibility of analyzing data with a number of pairs of resonances. The effective areal density of the main element, which is required for the calculation of the self-shielding factors, can be derived from a least squares analysis. Using the areal density as a free parameter, consistent weight ratios can be obtained; see, for instance, the analysis of the Buggenum sword (Postma et al. 2010).

An important step in the analysis is the extraction of the number of counts in resonance peaks. In the case of an isolated resonance that is free from overlap with other resonances and a simple background, it can be done by summing the counts of the channels of the peak by setting limits as far out in the wings as possible and by subtracting the background component. It becomes more complicated if the resonance has a strong structure due to multiple interaction events (scattering followed by capture) or if overlap with other resonances occurs. In such cases a shape analysis should be carried out: either a relatively simple shape analysis based on pseudo-Voigt functions, or on more complicated codes like REFIT (Moxon and Brisland 1989).

Neutron resonance transmission analysis (NRTA)

When a neutron traverses an object, neutrons are removed by capture and scattering interactions. As a consequence, the spectrum after transmission will show dips at resonance energies. Again, elements can be recognized from the locations of the resonances, while the areas of the dips provide information about the amounts of these elements.

NRTA requires a neutron-sensitive detector. A suitable neutron detector is a Li-glass scintillator that is enriched in ^6Li , which has a large capture cross-section for the reaction $^6\text{Li} + n \rightarrow ^3\text{H} + ^4\text{He}$. The energy of this reaction generates a light flash (scintillation) in the glass, which is detected by a photomultiplier viewing

the Li-glass. Experimentally the transmission is obtained from the ratio of the result of a sample-in and sample-out measurement, both corrected for losses due to dead time and background contributions. Since the experimental transmission is a ratio of TOF-spectra obtained with the same detector and in the same geometry, it is an observable that is independent of the detector efficiency and neutron flux. Ideally the measurements are performed in a good transmission geometry such that the experimental transmission is almost a direct measure of the theoretical transmission, which is given by:

$$T(E) = \exp\left(-\sum_k n_k \sigma_{tot,k}^D(E)\right) \quad (4)$$

where $\sigma_{tot,k}^D$ is the Doppler broadened total cross-section and n_k is the areal number density (or number of atoms per unit area) of nuclide k in the sample. Measurements in good transmission geometry can be realized by properly collimating the neutron beam such that all detected neutrons have traversed the sample and neutrons that are scattered by the sample are not detected. Under these conditions the composition of the sample can be derived absolutely without any calibration requirement (Schillebeeckx et al. 2014). This is one of the main advantages of NRTA compared with NRCA. In the 100 keV to 1 MeV region, NRTA can also be applied to determine the amount of light elements. In addition, using a position-sensitive neutron detector, NRTA can be a useful basis for an imaging method with element recognition based on resonances (Perelli Cippo et al. 2011). On the other hand, the sensitivity of NRCA to detect impurities and trace elements, even in the ppm region, is much higher. This is discussed below.

TOF resolution

The experimental observable of both NRCA and NRTA measurements will be broadened due to the finite time resolution of the TOF spectrometer, and in the case of NRTA, of the neutron detector. Evidently the impact of the corresponding response functions decreases with increasing flight path distance. The response function of both the TOF spectrometer and neutron detector

can be derived from Monte Carlo simulations. The former is primarily determined by the neutron transport in the target-moderator assembly. In general, the TOF resolution of a pulsed neutron source based on photonuclear reactions is superior compared with the one based on spallation reactions (Schillebeeckx et al. 2014). The response function at a spallation source is more complex. In addition, their response functions have more asymmetric shapes and are affected by a contribution with a long tail.

The response of the neutron detector is strongly dominated by the attenuation of the neutron beam in the neutron-sensitive material of the detector; for example, the response of a Li-scintillator neutron detector is defined by the thickness of the ${}^6\text{Li}$ -glass.

Example of NRCA and NRTA applied together

As an illustration of NRCA and NRTA, an example in which both methods were applied is presented. It concerns a fragment from a cauldron, a seventh century BCE Etruscan bronze vessel, excavated in Satricum, 60 km south of Rome. Spectrums of both methods are shown in Figure 1. In the capture spectrum, resonance peaks are observed, while these resonances appear as dips in the transmission data. The most prominent peaks and dips are due to resonances of copper, tin, arsenic, antimony, silver, and indium.

The ratio of counts in two resonances of the same element varies with the thickness of the object, in the case that self-shielding effects are different (that is, when a weak resonance is compared with a strong resonance). This occurs for the resonances of copper at 230 and 578 eV. With a calibration curve, obtained with a series of copper sheets of several thicknesses, an areal density of 0.54 (4) g/cm² for Cu was derived from the capture data. (Postma et al. 2003). This areal density is in good agreement with the value of 0.55 (2) g/cm² obtained from transmission data. The latter was obtained without the need for any additional calibration data.

Weight ratios $W_{\text{Sn}}/W_{\text{Cu}}$ and $W_{\text{Ag}}/W_{\text{Cu}}$ derived from NRCA and NRTA measurements are compared in Table 1. They are in good agreement. The uncertainties are only due to counting statistics.

Table 1 Composition of the *cauldron* fragment as determined by NRCA and NRTA. The quoted uncertainties are only due to a propagation of counting statistics uncertainties.

Method	Weight ratio			
	W_{Sn}/W_{Cu}	W_{As}/W_{Cu}	W_{Sb}/W_{Cu}	W_{Ag}/W_{Cu}
NRCA*	0.2681 (13)	0.004333 (16)	0.00252 (27)	0.00114 (9)
NRTA**	0.243 (7)			0.001112 (10)

* calibration method, ** absolute determination

Figure 1 Capture and transmission spectrums obtained at the GELINA facility as a function of neutron energy for the cauldron sample. For the capture measurement, a flight path of 12.5 m was used. The transmission experiment was carried out at a station with a 10 m flight path. Elements with isotopic numbers are indicated at several resonances which were used for the analysis. Published with permission of Springer, from Postma, Schillebeeckx, and Halbertsma (2004), “Neutron Resonance Capture Analysis of Some Genuine and Fake Etruscan Copper-alloy Statuettes.” *Archaeometry* 46 (4), 635–46.

The values derived from NRTA are obtained in an absolute way. However, they depend on the quality of the nuclear data, that is, the resonance parameters used in the analysis from Tsuchiya et al. (2014).

Figure 1 shows that a trace element such as indium can be detected by NRCA. The relative amount of indium, $W_{In}/W_{Cu} = 79 (4) \times 10^{-6}$, derived from the capture data is not sufficient to create an observable dip in the

transmission spectrum. In conclusion, NRCA has a more favorable detection limit to identify trace elements compared with NRTA. The advantage of NRTA is the absolute way to derive directly the amounts of elements in objects.

It has been shown in several of the NRCA projects that it is of value to implement information derived from X-ray or neutron diffraction (see NEUTRON DIFFRACTION (ND)) for the benefit of the analysis of archaeological objects (Schut et al. 2008; Postma et al. 2011).

Some NRCA results

NRCA has been successfully applied to various kinds of archaeological objects. Some of these results are briefly mentioned. For all the objects mentioned below, a sheet of cadmium was used to remove neutrons below 0.7 eV from the beam, and a sulfur disk was used to remove high-energy neutrons in order to reduce activation to a very low level. The objects could always be returned to the owners the same or next day after the run with negligible activation.

The first extensive study by NRCA concerned statuettes and some small parts from the famous collection assembled by the Count Corazzi of Cortona (Italy) in the eighteenth century. This collection is said to be from the Etruscan period. It now belongs to the National Museum of Antiquities in Leiden, the Netherlands. However, questions were raised concerning the origin of several of these items. For this reason, NRCA experiments were carried out on a series of these artifacts. It turned out, on the basis of their compositions, that five of them are from later times. They are fakes or imitations, possibly made during the Renaissance (Postma, Schillebeeckx, and Halbertsma 2004).

A study of parts of water taps excavated in the Netherlands showed the technical skills of the Romans in fabricating objects (Schut et al. 2008).

Several swords of the Middle Bronze Age were analysed. An extensive study of the Buggenum sword from the National Museum of Antiquities in Leiden should be mentioned, which also includes neutron diffraction (see NEUTRON DIFFRACTION (ND)) research (Postma et al. 2010).

A study of socketed axes of the Geistingen type showed that bronze objects are not always made from tin-copper alloy, but in this case they are made from a complex alloy containing large amounts of nickel, antimony and arsenic, together with about 25 wt.% in copper (Postma et al. 2011).

Non-Stable Isotopes in Archaeology

ZOFIA ANNA STOS-GALE

University of Oxford, UK; University of Gothenburg, Sweden

Introduction to lead isotopes

Lead occurs in major amounts not only in lead–zinc–silver ore deposits, but also in lesser amounts in copper and iron ore deposits; it occurs in at least parts per million levels in all rocks and non-metallic minerals. Terrestrial lead consists of four stable isotopes: ^{208}Pb , ^{207}Pb , ^{206}Pb , and ^{204}Pb . The isotope ^{204}Pb is non-radiogenic in origin; it was incorporated into the Earth when it was formed from the proto-solar system about 4.57 thousand million (10^9 or billion) years ago. The other three lead isotopes (LIs) derive from the radioactive decay of longlived naturally radioactive isotopes of uranium (U) and thorium (Th):

At first U, Th, and Pb were uniformly mixed together in the hot, liquid Earth. When the Earth started to cool, the relative concentrations of these elements differentiated from place to place. During those years, the U and Th were continuously producing more of ^{208}Pb , ^{207}Pb , and ^{206}Pb , but in somewhat different amounts. A more important stage of differentiation of the amounts of the isotopes came with the process of ore formation starting about 3 billion years ago when, due to the high temperatures and differences in chemistry, U and Th were separated from lead. Therefore, in most minerals the U/Pb and Th/Pb ratios are so low that their lead isotopic compositions have not changed appreciably with time since it was

laid down in a mineral deposit. These “frozen” in time lead isotope compositions can be used for dating of the ore- and rock-forming processes.

If there are no additional events influencing the lead isotope compositions in the ore mineral or rock, then this system is referred to as single-stage radiogenic growth of lead in a closed chemical system. It can be characterized by growth curves with associated values of $^{238}\text{U}/^{204}\text{Pb}$, as measured today for the parent U–Pb system, and $^{232}\text{Th}/^{204}\text{Pb}$ ratios for the parent Th–Pb system. This model is called the Holmes-Houtermans model; its more developed versions were proposed by Stacey and Kramers, and Cummings and Richards (see Faure 1986). Using these mathematical models, it is possible to calculate, from the measured LI compositions of ore minerals, so-called “model ages” of the ore deposits. The growth curve of the LI ratios related to the age of the ore deposits is clearly represented on the plots of ratios of $^{206}\text{Pb}/^{204}\text{Pb}$ (x axes) and $^{207}\text{Pb}/^{204}\text{Pb}$ (y axes) (Figure 1a).

The isotope compositions of the lead in the ores depend on the age of their formation, the original amounts of uranium and thorium, and the further geological history of the deposit (mixing with ore-forming fluids, redeposition, later metamorphism). Therefore, in principle, minerals of different geographical origin, formed at different geological periods, have a high probability of displaying different LI compositions.

The measurements of lead isotope compositions

Since the 1970s a standard method used for LI analyses has been thermal ionization mass spectrometry (TIMS). The LI ratios are measured using exactly specified chemistry of lead separation and deposition, and methodology for running the mass spectrometer; the raw data are corrected by comparisons with lead isotopic standard US NBS (NIST) SRM 981. Strict adherence to this methodology allows us to measure LI compositions with very great accuracy (usually

Figure 1 (a) Graphic representation of the Holmes-Houtermans model ages of ore deposits (A, B, C, etc.) calculated from their lead isotope ratios. This model demonstrates that not only ores of different ages, but also ores of the same age can have different lead isotope compositions due to the different initial amounts of uranium and thorium in the ore-forming fluids (μ values) represented by the outer curves. The straight lines indicate ores of the same age. (b) and (c) Plots of two sets of independent lead isotope ratios representing data for copper ore deposits in the Mediterranean, which were exploited in the Bronze Age, and the second millennium BCE copper ingots of the "oxide" shape that were found in Cyprus, Greece, Italy, Egypt, Turkey, and Bulgaria. All these ingots have lead isotope ratios and trace elemental compositions fully consistent with the Cypriot copper ores.

better than 0.1% for annual runs of the SRM 981 standard) and very good reproducibility of measurements taken in different laboratories.

Further developments in instruments measuring LI compositions came with the introduction of instruments that use laser ablation of the sample and ionization of lead in a plasma source with multiple Faraday cups as ion collectors: multicollector inductively coupled plasma mass spectrometers (MC-ICP-MS). These allow analyses of much smaller samples with very high overall accuracy (commonly 0.01%).

The TIMS and MC-ICP-MS are the only methods of measuring LI compositions that are suitable for archaeological provenance research. The other instruments that can measure the LI ratios (e.g., quadrupole mass spectrometer (Q-ICP MS) or time-of-flight (ToF) mass spectrometers) have much poorer accuracy due to substantially larger and less reproducible mass fractionation.

Application of lead isotope compositions in archaeology

In 1967 Robert Brill and John Wampler published comparisons of the LI compositions of ancient lead artifacts with those of ore deposits. Quite soon, LI provenance studies broadened to include analyses of glass, glazed pottery, silver coins, and artist's pigments. In 1982 the first paper was published suggesting use of LIs for finding sources of Bronze Age copper artifacts (Gale and Stos-Gale 1982), and that considerably raised the interest of archaeologists in this method for provenancing Bronze Age metals. In the following years archaeometallurgical projects conducted by several research groups developed the methodology by analyzing ores and metals to test the possibility of changes of lead isotope compositions during the smelting and refining processes, or during the addition of tin to make bronze. The results of these experiments proved that metallurgical processes do not change the original LI compositions of metals and pigments. Since the early 1980s several large research projects into sources of copper, lead, and silver in the Bronze Age were undertaken. These projects were based on simultaneous collection of mineral samples from ore deposits, and samples of ancient artifacts

from archaeological excavations and museums, combined with archaeometallurgical surveys of ancient mines and slag heaps, and provided LI, geochemical and chronological information about the earliest copper and lead/silver ore extraction in the Old World (e.g., Stos-Gale and Gale 2009; Artioli et al. 2014; Pernicka, Lutz, and Stöllner 2016).

Since there is a necessity to take small samples from artifacts for lead isotope analyses (1–20 mg), the scope of the research can be limited by the reluctance of museum curators and archaeologists to allow sampling of precious artifacts. For MC-ICP-MS it might be possible to use laser ablation from the surface of the artifact to minimize the damage, but there is no possibility of the use of a mass spectrometer in a museum or on archaeological site, since no machine of the required accuracy has yet been developed in a sufficiently portable format.

Methodology of interpretation of lead isotope data

The identification of origin of archaeological materials requires comparisons of their lead isotope ratios with the ores, and therefore an extensive lead isotope database for ore deposits is the most important requirement. Calculating the geological age (model age) from the lead isotope ratios of the ancient artifact and comparing with the known ages of ore deposits is not sufficient, due to the variations in lead isotope compositions of ores not related to their age (e.g., the U and Th contents and other geological processes). So far there is only one open LI database on the internet; OXALID makes available data for Mediterranean ore deposits and Bronze Age metals (University of Oxford 2017). The other datasets are still only available in published papers. Currently there are about 8,000 published lead isotope results for ores relevant to Old World archaeology.

In principle, the ancient artifact can be regarded as fully consistent with an origin from a given ore deposit if the three independent lead isotope ratios of the artifact are each identical to the lead isotope ratios of the ores from this deposit. So, the initial stage of identifying the possible sources of archaeological artifacts

relies on finding, for each artifact, the identical data for ores. This can be done by calculating the Euclidean distances between the three independent lead isotope ratios of the artifact and all available ratios for ore samples. However, this is only a preliminary step to select a group of ore deposits that have lead isotope ratios within the appropriate range. Following this initial selection, it is necessary to check the geochemistry and history of exploitation of the possible ore deposits and eliminate those which cannot have been used as a source of given material on geochemical or historical grounds.

Plotting the lead isotope ratios of the artifacts and ores on two lead isotope diagrams to include all three independent lead isotope ratios provides the most accurate visual representation of the consistency of lead isotope ratios of the ores and artifacts. The lead isotope ratios used for such plots in geochronology always relate to ^{204}Pb , as seen in Figure 1b and c: $X = ^{206}\text{Pb}/^{204}\text{Pb}$, $Y_1 = ^{207}\text{Pb}/^{204}\text{Pb}$ and $Y_2 = ^{208}\text{Pb}/^{204}\text{Pb}$. However, because the isotope ^{204}Pb in naturally occurring lead is always present in much smaller quantities than the other three radiogenic isotopes, the measurements of the ratios to ^{204}Pb are less accurate. Therefore, in principle, the plots of radiogenic ratios can show more accurately the comparative positions of data points. For this reason, in the research publications of archaeological applications of lead isotope measurements, most often the two plots represent the data along the axes: $X = ^{207}\text{Pb}/^{206}\text{Pb}$, $Y_1 = ^{208}\text{Pb}/^{206}\text{Pb}$ and $Y_2 = ^{206}\text{Pb}/^{204}\text{Pb}$. Some researchers also used other ratios, but essentially the choice of lead isotope ratios for comparative plots always leads to the same conclusions if all three independent ratios are considered.

Problems and additional help with interpretation of lead isotope data

Not all ore deposits have different ranges of lead isotope ratios, and therefore there are common instances of overlap of the data for deposits from different geographical regions. In such cases, there are two main points that must be considered: the geochemistry of the ores in each of the deposits, and the probability of their

exploitation in the period under consideration. Therefore, it is necessary to compare the elemental compositions of ancient artifacts with the geochemistry of the ores and the periods of exploitation of the selected ore deposits. The elemental compositions of metals reflect the type of ore mineral used for smelting, and typical impurities are often characteristic of certain deposits. Furthermore, the trace element signatures can discriminate metal groups that not only reflect various ore types, but are important for comparison with previously analyzed artifacts from various regions and certain chronologies. However, it is important to stress that the identical lead isotope characteristics of a group of metals do not guarantee that their elemental characteristics will also form a group, and vice versa.

There are two other serious problems that can affect the provenancing of ancient metals by their lead isotope ratios: one is the possibility of addition of lead to the metal (copper, tin, bronze, or silver), and the other is remelting of metal pieces from different locations and making a new artifact from the metal obtained in this way. The addition of lead should be considered if the lead content is above 1–2%. Then the comparisons must be made with the sources of lead or copper/lead ores. The problem of mixing can be assessed by examining the distribution of the data points on the lead isotope plots: each metal obtained from mixing two other sources will plot somewhere along a straight line between the data points representing these other sources.

It is sometimes concluded in the literature that lead isotope provenance methods allow only “rejection” of a source of the ancient metal, and not a positive conclusion of its provenance. This is far too weak an assessment of this provenance tool. The lead isotope compositions, particularly combined with geochemical and archaeometallurgical data, give much more information than a simple rejection of a source on the grounds of difference between lead isotope ratios of ores and the ancient metal. While the lead isotope data do not allow a definite positive assignment, they tell us which assignments are possible, and that this information should be taken further to look at which of the ore deposits can be considered as

sources, particularly if evidence exists that these were exploited at the times in question.

The impact of lead isotope provenance studies in archaeology

Figures 1b and c show an example of a comparative plot of lead isotope ratios for some of the copper ore deposits in the Mediterranean that were exploited in the Bronze Age, and those measured for over 100 ingots of copper of a very specific shape (“oxhide ingots”) dated to the Late Bronze Age and found on various sites in southern Europe, Turkey, and Egypt (Stos-Gale et al. 1997). This plot demonstrates clearly that all analyzed oxhide ingots are consistent with the origin of the ores from Cyprus. This conclusion was at first highly surprising for archaeologists, since many regions where the ingots were found (i.e., Sardinia, Egypt, Greece) exploited their own copper ores in the Late Bronze Age, but chemical and archaeological evidence fully supports this conclusion. The lead isotope research aimed at provenance of Bronze Age metals brought some other unexpected results concerning the exploitation of copper in Europe and import of copper into Scandinavia (e.g., Ling et al. 2014; Artioli et al. 2014; Cattin et al. 2009; Gale et al. 2003).

Strontium as tracer of origin

Strontium (Sr) is a member of the alkaline earths and is known to replace calcium in many minerals. Strontium, therefore, is dispersed in all calcium-bearing minerals, its salts are dissolved in fresh and seawaters, and it is present in sedimentary and igneous rocks. Strontium compounds in the soil and water enter plants, animals and humans through direct uptake or through the food chains. Strontium has four naturally occurring isotopes: ^{88}Sr , ^{87}Sr , ^{86}Sr , and ^{84}Sr , all of which are stable. Their relative abundances are 82.5%, 7%, 9.9% and 0.56% respectively. The isotopic abundances of strontium are variable because of the formation of radiogenic ^{87}Sr through the decay of terrestrial ^{87}Rb with a half-life of 4.88×10^{10} . For this reason, the precise composition

of strontium in a rock or mineral that contains rubidium depends on the age and Rb/Sr ratio of that rock or mineral. Strontium isotopes can be measured very accurately using TIMS and MC-ICP-MS; the typical overall accuracy for TIMS is $\pm 0.01\%$ in measuring the isotopic ratio of $^{87}\text{Sr}/^{86}\text{Sr}$ for about $0.5\text{ }\mu\text{g}$ of Sr extracted from samples of minerals. TIMS has been used for longer than the other instruments and is the most routinely used procedure for strontium isotope analyses. Although using the TIMS is time-consuming (each analysis could take 1–2 h), it requires less strontium compared with other solution-based analyses, and has the highest reproducibility and precision.

Rb/Sr dating is used in geochronology, but the characteristic Sr isotope compositions of minerals from possible sources of raw materials can be used for finding the origin of artifacts made of natural sedimentary rocks, bone, and ivory. The earliest research applying Sr isotopes combined with sulfur to provenancing gypsum used in Mycenaean and Minoan palaces was published in 1988 (Gale et al. 1988).

Isotope ratio analysis of the radiogenic strontium is a well-established procedure used in geology, and therefore a considerable database of Sr isotope ratios in rocks in different locations—regional isoscapes—are available for archaeological projects. $^{87}\text{Sr}/^{86}\text{Sr}$ values change little as they pass from weathered rocks through soils to the food chain, and it has been proven that the isotopic compositions of strontium deposited in human teeth and bones reflect the composition of the natural environment that supplied the food consumed by the individuals. Therefore, analyses of radiogenic strontium isotopes combined with application of other scientific techniques (for example, DNA, as well as oxygen and lead isotopes) in either hard and/or soft tissue allow the reconstruction of ancient human mobility at the individual level. One of the most iconic projects based on this methodology was the study of the remains of the Egtved Girl, in a Bronze Age oak coffin burial in Denmark (Frei et al. 2015).

Nuclear Magnetic Resonance (NMR)

MARIA BAIAS

New York University Abu Dhabi, UAE

Nuclear magnetic resonance (NMR) is an analytical technique widely used for chemical analysis, materials science, medical imaging, chemical engineering, well logging, process and quality control, and more recently for heritage. This technique is based on the NMR phenomenon, which works by irradiating atomic nuclei with radiofrequency (RF) waves, when the sample is placed in an external magnetic field (Blümich 2000; Callaghan 1991). The magnetic field is usually attained in superconducting magnets and the currently available NMR magnets can have magnetic fields varying between 1 T and 28 T. Superconducting magnets are used both for solution-state and for solid-state NMR, and increased magnetic fields are constantly opening the path to new applications and investigations of more complex systems. In contrast to the superconducting high-field NMR magnets that produce a homogeneous magnetic field, in which the sample is inserted, NMR at low fields can be achieved in inhomogeneous magnetic fields produced by permanent magnets, and in this case the sample can be external to the magnet.

In chemical sciences, NMR is used for determining molecular structures and for gathering information about dynamics in the sample. In materials science and chemical engineering, NMR has been applied for the investigation of a wide range of materials, such as polymers, glasses, zeolites, pharmaceutical polymorphs, energy materials, materials for catalysis and gas storage, superconductors, liquid crystals, food, minerals, and wood. NMR is also a powerful tool for structural biology, where it is applied for studying protein structure and dynamics, protein folding and unfolding, and protein–drug interaction, as well as for the investigation of viruses,

DNA, and RNA. Its contribution to medicine comes under the form of magnetic resonance imaging (MRI), where MRI magnets are utilized both in hospitals and in research centers to study the body by recording three-dimensional images of different anatomical parts such as the brain, spine, and abdomen. MRI scans help with the identification of tumors and can help diagnose various diseases such as cancer, multiple sclerosis, and strokes. NMR is used in well logging for oil reservoir exploration, extracting information regarding rock porosity and pore distribution, rock composition and type, and quality of the fluid—oil, gas, or water. With the development of unilateral low-field NMR sensors, NMR has been increasingly applied to process and quality control. Thus, unilateral NMR is an ideal tool for the nondestructive characterization of materials in industry and it has been applied for the quality control and analysis of rubber products, extracting information on the morphology and domain sizes in semicrystalline polymers and understanding the aging mechanism of polyethylene pipes, and unilateral imaging can be applied for identifying defects in materials. The most relevant application of unilateral NMR in the field of cultural heritage studies is that it is possible to analyze not only portable objects, but also large artifacts or even architectural components directly on site. In the field of heritage, NMR can nondestructively explore historical artifacts, which can lead to understanding the science behind the creation of these treasured items—paintings, frescoes, parchments, historical buildings, musical instruments, ancient mummies, and other artifacts.

NMR is the physical phenomenon that occurs when atomic nuclei that possess a nuclear spin are irradiated by RF pulses while the sample is positioned in a static magnetic field. In the absence of an external magnetic field there is a random distribution of the nuclear spins leading to a null net magnetization, where the net magnetization—or macroscopic magnetization—is represented by the sum of the magnetic fields of each spin. When these nuclear spins are placed in an external magnetic field, they align with the external magnetic

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0415

field, either parallel or antiparallel, where the spins with parallel orientation populate the lower energy levels, while the spins with antiparallel orientation are found on higher energy levels. Resonance occurs when the sample in the static external magnetic field is irradiated with an RF energy corresponding to the energy difference between the two energy levels; the higher the magnetic field, the higher the resonance frequency—for example, at a magnetic field of 9.4 T, the protons resonate at a frequency of 400 MHz, while when increasing the field to 23.5 T, the proton frequency also increases to 1 GHz. The result of RF irradiation is the excitation of the nuclei from the low energy levels to the higher energy levels. This is recorded in NMR experiments under the form of a free induction decay (FID)—the representation of the NMR signal under the time-domain. A Fourier transform (FT) of the FID shifts the representation of the NMR signal from time domain to frequency domain, thus yielding the NMR spectrum.

NMR is a very sensitive tool to local structure, having the advantage of being able to detect the different resonance frequencies of nuclei in different environments, and they are illustrated in a one-dimensional NMR spectrum as peaks on a frequency scale. Depending on the local environment of each nucleus, its NMR corresponding peak can be found at different resonance frequencies in the spectrum, referred to as chemical shifts. Chemical shifts are a very useful tool for structure determination. In one-dimensional spectra, chemical shifts are used to identify the different possible chemical groups in a molecule; however, the larger the molecule, the more crowded the spectrum, which leads to overlap of peaks and difficulties in assigning the spectra. This obstacle is overcome by increasing the number of dimensions in the NMR spectrum and recording multidimensional spectra, which became possible with the invention of two-dimensional correlation NMR spectroscopy (Ernst, Bodenhausen, and Wokaun 1987). Higher-dimensional NMR spectroscopy opens the path to structure determination of larger molecules, including three-dimensional structure determination of proteins, and even full crystal structure determinations when the sample is a powdered solid. While solution-state NMR spectra are characterized by sharp signals,

when investigating solid samples, chemical shift anisotropies and strong dipolar interactions present in these samples broaden the NMR spectra; therefore no chemical shift information can be discerned. In order to achieve high-resolution solid-state NMR spectra, additional techniques have to be applied when working with solid samples. One of these techniques is called magic angle spinning (MAS) and requires the powdered sample to be spun at high spinning speeds in a small cylindrical rotor about a spinning axis oriented at the magic angle (54.74°) with respect to the applied magnetic field. By spinning the sample at the magic angle, the effects of chemical shift anisotropy and dipolar coupling effects are removed (Hennel and Klinowski 2004) and resonances can be more easily resolved.

Other important NMR parameters that one can analyze are the nuclear spin relaxation times (longitudinal and transverse relaxation), J-couplings (through bond interactions), dipolar couplings (through space interactions), quadrupolar parameters, and self-diffusion coefficients.

Certain isotopes of chemical elements possess nuclear spins and, therefore, are NMR “visible”; examples of such isotopes are: ^1H , ^{13}C , ^{15}N , ^{29}Si , ^{31}P , ^{195}Pt , and so on with spin = $\frac{1}{2}$, and ^2H , ^7Li , ^{23}Na , ^{41}K , ^{51}V , ^{235}U , and so on with spin $> \frac{1}{2}$. Over 75 percent of the atomic nuclei that are NMR active possess spin $> \frac{1}{2}$; these are quadrupolar nuclei and they possess a quadrupolar moment arising from a nonspherical distribution of charge in the nucleus of nuclei with spin $> \frac{1}{2}$ (Ashbrook 2009). The natural abundance of various isotopes can range between 0 and 100 percent; thus, while nuclei such as ^1H and ^{31}P have a high natural abundance of 99.98 and 100 percent, respectively, other isotopes such as ^{13}C and ^{15}N have much smaller natural abundance of only 1.11 and 0.37 percent, respectively. The higher the natural abundance, the easier it is to measure certain spins over others. While NMR experiments can be recorded for the low natural abundance nuclei, the measurement time is much longer since the number of spins recorded in the experiment is much smaller. In order to reduce the experimental time there are techniques that allow for NMR measurements to be done on the nuclei with lower natural abundance. The experimental time can be reduced considerably by isotopically

enriching—or labeling—the sample with the desired isotope. A sample can be uniformly or specifically labeled with one or more isotopes. In a uniformly labeled sample, all atoms of a selected chemical element are represented by a single isotope, for example, labeling all the carbon atoms of a molecule with the ^{13}C isotope. When selectively labeling a sample, the labeling is targeted towards specific sites in the molecule, for example, labeling only some of the carbon atoms of a molecule with the ^{13}C isotope, or labeling only certain amino acids of a protein with the ^{15}N isotope. Site-specific labeling is a useful technique when dealing with crowded spectra with many peaks; such is the case of proteins, where hundreds of amino acids give rise to hundreds of overlapping resonances in the NMR spectra. Targeted labeling of certain residues will both simplify the spectra and help assign the resonances corresponding to the labeled amino acids, and therefore help with the structure determination of the protein backbone, which makes isotopic labeling an indispensable tool in biomolecular NMR spectroscopy.

There are ongoing developments in the field of NMR to increase the sensitivity and decrease the experimental time. Different approaches for signal enhancement include dynamic nuclear polarization (DNP) and the use of hyperpolarized gases, such as hyperpolarized ^{129}Xe . Spin manipulations by complex sets of RF pulses to create new pulse sequences that allow for more information to be extracted from the NMR experiments are being developed, and, more recently, the use of magnetic field gradients in combination with complex pulse sequences for a more rapid acquisition of two-dimensional spectra are being exploited to shorten the experimental time. Due to advancements in developing the DNP technique, it is increasingly exploited for applications in both solution-state and solid-state NMR experiments. DNP makes use of the larger polarization of the unpaired electron spins when irradiating a sample with microwaves, and when this polarization is transferred to the surrounding nuclear spins it leads to an enhancement in nuclear polarization, and therefore to an enhancement of the sensitivity of the solid-state NMR experiments by several orders of magnitude (Rosay, Blank, and Engelke 2016). In a similar way, hyperpolarized noble gases can be used in NMR and MRI for experiments at varying magnetic fields—from

the large magnetic fields created in superconducting magnets to very low fields, such as the Earth's magnetic field. The main advantage of using hyperpolarized gases is the large nuclear spin polarization created through spin exchange optical pumping, polarization which can be then transferred to other nuclei, thus enhancing the sensitivity of the NMR experiments. While DNP and hyperpolarization make use of high polarization transfer to the nuclear spins, methods such as ultrafast multidimensional NMR were developed to dramatically reduce the speed of acquisition of multidimensional NMR spectra, resulting in an experimental time of less than one second for a two-dimensional NMR spectrum acquired in only one scan. This method is based on spatial encoding (selective excitations of spins located at different positions in the sample) and makes use of the magnetic field gradient for the acquisition of signal (Freeman 2011). This technique is ideal for the investigation of fast biochemical changes such as protein folding and unfolding, and for the online monitoring of chemical reactions.

In the field of archaeological sciences, different NMR techniques have been applied to study various samples from heritage objects and sites. Solution-state NMR has been applied for the egg yolk identification and aging in mixed paint binding media, while solid-state NMR has been used to analyze a variety of samples relevant to heritage materials—parchments, stone materials from World Heritage sites, amphora residues, ancient wood samples, and so on. However, both solution- and solid-state NMR are invasive techniques, which require the removal of small parts, of the order of milligrams or micrograms, from the investigated object in order to be placed inside the superconducting magnet for the NMR measurements.

A major breakthrough in the application of NMR in heritage studies came with the development of low-field NMR magnets. These instruments are portable unilateral sensors that allow for the in-situ noninvasive investigation of arbitrarily sized objects. These sensors combine open magnets and surface RF coils to excite a sensitive volume inside the object under investigation that is external to the sensor (Eidmann, Blümmer, and Blümich 1996). Examples of portable NMR sensors include the Bruker Profiler[®] and the Profile NMR-MOUSE[®] (MOBILE Universal Surface

Explorer). A challenge arising from the simple magnet design of these portable sensors is the inhomogeneous magnetic field; however, one can use these sensors to probe ^1H longitudinal and transverse relaxation times as well as diffusion times at different depths in the sample, since these parameters are not affected by the magnetic field inhomogeneity. These sensors have two major advantages of high importance for archaeological research—the portability and the noninvasive nature of the technique—enabling scientists to explore a wide range of precious historical artifacts: paintings, frescoes, mosaics, parchments, historical buildings, ancient wood, musical instruments, ancient mummies and bones, and other artifacts (Blümich et al. 2010).

The portable nature of these sensors allows for the NMR measurements to be done on site, at the location where the objects of interest are hosted, such as museums and archaeological sites. Having portable research instruments is essential when conducting scientific investigations at archaeological sites because the object of interest is part of a historical building and cannot be relocated; therefore it needs to be investigated on site. A relevant example is the use of the NMR-MOUSE to map the state of conservation of different frescoes and mosaics from ancient Herculaneum, Italy. Of equal importance is the need to perform the measurements under certain physical conditions crucial to ensure the preservation of the sample during the experiments. This is the case of a study done on Ötzi—the Iceman—a glacier mummy, which is preserved at a constant temperature of -6.12°C and constant humidity of 99.42 percent inside a cold room at the museum in Bolzano, Italy. The NMR-MOUSE is ideal for investigations of Ötzi because the experiments can be performed in the cold room of the museum where the mummy is hosted without the need to relocate the mummy.

The second major advantage of these sensors is their noninvasive nature, and experiments such as relaxation, diffusion, and proton density measurements can be used to characterize heritage in a nondestructive way. This opens the path to studying objects as diverse as paintings, mummies, parchments, and musical instruments, objects that could not be previously investigated by other invasive methods.

A special feature of the Profile NMR-MOUSE sensor is its ability to record experiments at different depths inside the object of interest, by collecting depth profiles, where proton densities can be determined at different depths in the sample with a depth resolution as low as $10\text{ }\mu\text{m}$. This allows for the use of portable NMR to monitor the state of precious heritage objects both at the surface and inside the objects, gaining a more comprehensive understanding of the overall state of conservation of the object.

The large variety of NMR methods available for studying samples under solid-state and solution-state, where experiments can be recorded at a broad spectrum of magnetic fields, ranging from very high fields to low magnetic fields, and even NMR experiments done in the Earth's magnetic field prove that NMR is an outstanding technique with widespread use in multiple areas of science and technology. Of highest importance for the field of archaeology is unilateral portable NMR, a low-field NMR technique that enables a noninvasive characterization of precious heritage objects.

Optical Spectroscopies

DORIS MÖNCKE

Theoretical and Physical Chemistry Institute, National Hellenic Research Foundation, Greece

Optical spectroscopy allows the identification of pigments (see CHARACTERIZATION OF PIGMENTS) such as those found in many paintings, frescoes, and textiles (see TEXTILES), and even the concentration of dissolved absorbing ion species in transparent materials can be determined. For glasses (see GLASS COLOR) and gemstones (see GEMSTONES) optical spectroscopy is well established and is usually used in the transmission mode. In reflectance mode, optical spectroscopy can be applied to semitransparent and opaque materials such as ceramics, glazes (see GLAZES, SLIPS, AND PAINTS), enamels, frescoes, and paintings, as well as dyes (see DYES) in textiles (see TEXTILES) (Tilley 2011).

Optical spectroscopy relies on the fact that certain molecules, ions, and metallic and semiconducting particles can absorb particular energies, that is, specific frequencies of the electromagnetic spectrum. Often, an electron of the valence orbital of a transition metal or rare earth ion is elevated from an energetic ground state to an excited level, which takes a certain amount of energy (EN, in J or eV):

$$EN = h\nu = \frac{hc}{\lambda} = hc\tilde{\nu} \quad (1)$$

where ν is the frequency (s^{-1}), $\tilde{\nu}$ the wavenumber (cm^{-1}), λ the wavelength (nm), h the Plank constant with 6.62×10^{-34} Js, and c the speed of light with 3×10^8 ms^{-1} . Spectra are usually recorded as a function of wavelength (nm), though only the wavenumber gives an energy linear scaling. Thus, when deconvoluting optical spectra with Gaussian bands, it is important to convert wavelengths into wavenumbers.

Figure 1a shows how different electronic configurations for ions in different oxidation states

and coordination split their valence orbitals into states of varying energies. Specific absorption bands are assigned to transitions between particular energy levels, which are named according to the spectroscopic term scheme. The energy between these levels determines the wavelength of the absorption maximum, while the intensity of the transitions depends on the ease of each transition. The transition probability depends on several selection rules, which consider the spin of the electrons and the parity of the wave functions. All d–d transitions are Laporte- or parity-forbidden, which reduces the transition probabilities and subsequently the absorption intensity. This rule is relaxed for noncentrosymmetric geometries, and consequently high intensities arise for absorption bands of tetrahedrally coordinated Co^{2+} ions. The transmission probability is quantified by the molar extinction coefficient ϵ (in $L\ cm^{-1}\ mol^{-1}$), which is listed in Table 1 for typical ions in soda–lime–silicate glasses. Charge-transfer (CT) transitions (see Figure 1b) of an electron from the complexing ligand to the metal cation are Laporte-allowed and as a consequence they have much higher transition probabilities (ϵ of several thousands) (Duffy 1990; Tilley 2011; Möncke et al. 2014).

Many polyvalent ions can have different roles in glass science as either a colorant (see GLASS COLOR) or a opacifier, decolorant, fining agent, or impurity. The ions' valence can resolve the original function of these elements in glasses, while the redox ratio of a polyvalent ion might also hint at production technologies.

Different methods are available for obtaining optical spectra. The abilities and limitations of different instruments from the laboratory to portable equipment, including set-ups working in reflection or transmission mode, are briefly described here. Commercial laboratory instruments work well for glass and ceramic fragments, single mosaic *tesserae*, and other small objects which (1) fit in the sample chamber and (2)

Figure 1 Schematic of different electronic transitions: (a) d–d transitions, typical of dissolved transition metal ions in glasses. Valence and coordination determine orbital splitting (ΔE_o ; octahedral energy splitting) and subsequently absorbed wavelengths and color of material; (b) CT transition from anion to cation in the example of a sulfur–ammonium complex; (c) intervalence CT transition (IV-CT) between two cations of different charge; (d) band scheme of molecular orbital (MO) theory which is often used when discussing organic materials (LUMO, lowest unoccupied molecular orbital; HOMO, highest occupied molecular orbital); (e) schematic of plasmon-resonance; (f) band model, when many energy states are placed very close in energy and the diverse MO bands from (d) or energy levels discussed in (a) merge into energy bands. This depiction applies to semiconductors (including, e.g., CdSe), or when valence and conduction bands overlap, or to metals (including Ag, Au, and Cu nanoparticles).

can be brought to the laboratory. However, for larger objects, immovable pieces such as church windows, frescoes, and objects from valuable collections, portable spectrometers are an alternative option.

In transmission mode, spectra can be evaluated qualitatively, identifying absorbing ions, but also quantitatively for the colorants' concentration. The transmittance T is usually given as the ratio of the intensity of the probe beam passing through the instrument path without a sample

I_o , relative to the intensity of the corresponding beam passing through the sample I_t :

$$T = \frac{I_t}{I_o} \quad (2)$$

For most commercial spectrometers, the measured wavelength range extends from 200 up to 3,000 nm. Transmission spectra are usually transformed into absorbance spectra for evaluation. Commercial instruments use the decadic logarithm when converting T to

Table 1 Typical colorants and their transition probability in soda–lime–silicate glasses.

<i>Ion</i>	<i>Main transition(s) in visible</i>	<i>CN</i>	λ_{max} (nm)	ϵ (L cm ⁻¹ mol ⁻¹)	<i>Color</i>
Cu ⁺	d^{10}				Colorless
Cu ²⁺	d^9 ² E _g (D) → ² T _{2g} (D) tetragonal distorted	O _h	~800	~25	Sky blue
Co ²⁺	d^7 ⁴ A ₂ (F) → ⁴ T ₁ (P) split triplet	T _d	650 600 540	~180–200	Deep blue
Mn ³⁺	d^4 ⁵ E _g (D) → ⁵ T _{2g} (D) tetragonal distortion	O _h	480	~135	Deep purple
Mn ²⁺	d^5 ⁶ A ₁ (S) → ⁴ A ₁ (D)/ ⁴ E(D)	T _d	420	~0.3	Light orange
Fe ²⁺	d^6 ⁵ T _{2g} (D) → ⁵ E _g (D) tetragonal distorted	O _h	1050	~30–54	Light blue
Fe ³⁺	d^5 ⁵ E(D) → ⁵ T ₂ (D) ⁶ A ₁ (S) → ⁴ T ₁ (G), ⁴ T ₂ , ⁴ A ₁ / ⁴ E	T _d T _d /O _h	2000 380, 435, 555	~3–5	Yellow
Fe ³⁺ -O CT			210	~2500	Yellow
Fe ²⁺ -O CT			250	~5000	
Fe ³⁺ -S CT			410	~9000	Yellow to brown

absorbance A , though the natural logarithm is used when converting infrared (IR) spectra (see INFRARED REFLECTANCE SPECTROSCOPY) or when determining the band gap energy (Tilley 2011). Thus, it is always helpful to state the used modulus.

$$A_\lambda = \log \left(\frac{I_t}{I_0} \right)_\lambda \quad (3)$$

Absorbance is given in dimensionless units of absorbance. Optical density OD is the absorption normalized to a 1-cm-thick sample; thus OD is given in cm⁻¹. Though this term is out-of-date, it is helpful to normalize spectra to a defined sample thickness, since the coloring intensity depends on the probe beam's path through the sample. It is generally beneficial to mention the sample thickness.

UV-Vis-NIR spectrometers measure absorbance units of up to 2–3. New equipment might even reach absorption values of up to 10, providing that homogenous, plane parallel sample plates with optical grade polishing and 1 cm² or more dimensions are measured. Fiber optics allows analysis of much larger samples.

It is important to realize that the measured absorbance, or more precisely the attenuation

(ATT), is the sum of many different effects, such as the absorption of energy due to electronic or vibrational transitions A , reflection R , or scattering S .

$$ATT(\lambda) = A(\lambda) + R(\lambda) + S(\lambda) = 1 + E(\lambda) \quad (4)$$

E denotes the emission of radiation, for example from fluorescing ions. If emission is present, it adds photons to the measured light beam, and consequently, the analyzed transmitted light of some wavelengths might be higher in intensity than the intensity of the probe beam. The different effects are schematically depicted in Figure 2.

Especially when handling archaeological samples with inclusions, corrosion layers, or scratched surfaces, scattering will be significant. This is often reflected in an increased background absorption, which is often especially enhanced in the UV-Vis region.

Quantification of absorbing species is based on Beer–Lambert's law:

$$A = c d \epsilon \quad (5)$$

with the concentration of the coloring ion c (mol L⁻¹), sample thickness d (cm), and molar

Figure 2 Schematic of absorbing (A), scattering (S), reflecting (R), and emitting (E) centers or surfaces in a transparent material such as glass.

extinction coefficient ε ($\text{L cm}^{-1} \text{ mol}^{-1}$). This way of quantifying ion species is particularly important since typical techniques for the quantitative chemical analysis of glasses, such as inductively coupled plasma mass spectrometry (ICP-MS) (see ICP-MS AND MATERIAL ANALYSIS), X-ray fluorescence (XRF) (see PORTABLE X-RAY FLUORESCENCE SPECTROMETRY (PXRF)), and scanning electron microscopy energy dispersive X-ray spectroscopy (SEM-EDS) (see SEM-EDS AND MATERIAL ANALYSIS), only give the total element fraction but no information on the ions valence.

For quantification, only the absorption component of equation (4) is considered. For well-polished, homogenous transparent and plane parallel samples such as glasses (see GLASS COLOR), scattering can be neglected and reflectance can be accounted for by subtracting a calculated reflectivity value, based on the refractive index (Tilley 2011) with $n_{\text{air}} = 1$:

$$\text{with } R = \frac{(n_g - 1)^2}{(n_g + 1)^2} \quad (6)$$

For soda–lime–silicate glasses and air, the refractive index is $n_g \approx 1.5$, accounting for an average transmission loss due to reflectance of $R = 3\text{--}4$ percent.

For irregular sample geometries, the transmitted light will be refracted in different directions on the inner and outer surface instead of passing

straight through the sample. In this case, collecting all transmitted light beams requires the use of an integration sphere.

For very large or opaque samples, measurements are better obtained in the reflectance mode. Reflectance spectroscopy measures the reflectivity R , defined as the ratio of the intensity of the reference beam I_0 over the intensity of a fully reflected beam I_R :

$$R = \frac{I_R}{I_0}. \quad (7)$$

Only light wavelengths that are not absorbed are reflected from the sample. A pure white background such as polytetrafluorethylene (PTFE) or BaSO_4 is used for measuring the reference beam intensity I_0 .

Reflectance can be recorded either in direct or in diffuse mode. Whereas the direct mode only collects beams reflected at normal incident, the diffuse mode uses an integration sphere, collecting all reflected light beams, and therefore the sensitivity is generally higher when using a sphere.

Since the sample thickness is not probed, quantification can only be attempted semi-quantitatively through comparison with similar reference materials of known colorant concentration. Qualitatively, the same results can be obtained as in transmission spectroscopy. Any absorbing species can be identified and redox ratios of dissolved ions might be estimated from the relative band intensities.

Fiber optics reflectance spectroscopy (FORS) is an important variation employed in art and archaeometry (see *ARCHAEOLOGY*), since portable set-ups allow noninvasive in-situ measurements of very large objects (e.g., church windows, paintings, frescoes) or of precious museum pieces. FORS is an established technique for the identification of pigments (Aceto et al. 2014) and is increasingly used for glasses (see *GLASS COLOR*), glazes (see *GLAZES, SLIPS, AND PAINTS*) and enamels (Maltoni and Silvestri 2016).

The set-up of portable instruments is generally the same as described earlier, only that the light is passed through fiber optics between the sample and monochromator or detector, respectively. Measurements in transmission mode can also be realized if both sides of a large vase or large glass pane are accessible within the given length of the optical fibers.

The cost of such a set-up varies considerably between homemade and commercial laboratory equipment. Assembling a FORS set-up is relatively easy since only few components are required: a light source, spectrometer, and two optical fibers, one to illuminate the sample and the other to collect the diffused light. Equipment costs will be higher if the system's wavelength range is extended below 360 nm in UV or above 1000 nm in NIR.

Sensitivity is always lower in portable devices working with fiber optics compared to fully enclosed laboratory equipment, since any scattered light from the environment will negatively affect optical measurements. Enfolding the sample and FORS optical fiber heads by black velvet curtains helps to reduce light contamination.

Colors can be objectively described by various parameters, also called color space. This might be useful for publications or exhibition catalogs, like the visual comparison with reference materials such as Munsell or Pantone color cards. $L^*a^*b^*$ is a device-independent method, based on the CIE 1976 representation, which includes other typical gamuts, such as, for example, the RGB color model which is mostly used in computer screens (Tilley 2011). In the $L^* a^* b^*$ representation, L^* is the lightness, with $L^* = 0$ for the darkest black and $L^* = 100$ for the brightest white; a^* (+ red / - green) and b^* (+ yellow / - blue) are color channels. True neutral gray values are

found at $a^* = 0$ and $b^* = 0$. While $L^* a^* b^*$ values can be calculated from transmission spectra, direct measurements of transparent samples pose problems, since the sample thickness determines the perceived color.

Spectra of typical transition metal ions in glass (see *GLASS COLOR*) can be found in that entry, and in the literature (Möncke et al. 2014). Similar absorption bands are often found in crystalline pigments and gemstones (Fritsch and Rossmann 1987, 1988). A deep yellow to brown color in glasses can be caused by the intervalence-CT transition, from $S \rightarrow Fe^{III}$ in $[FeO_3S]^-$. The blue color in lapis lazuli is due to an interanion-CT transition in S_3^- .

Several databases are available for pigment identification. Spectral features such as the characteristic absorbing wavelengths and relative band intensities of the measured spectrum of unknown samples can be compared with well-known spectra. The online database of FORS spectra (<http://fors.ifac.cnr.it/index.php>) offers a high number of references of pure pigments. These spectra are not downloadable, whereas the spectra from the FORS Spectral Database of Historical Pigments in Different Binders (Cosentino 2014) can be downloaded as csv files. When analyzing paintings, many organic binders will contribute with the absorption of their complex organic molecules to the overall spectrum. Both listed databases account for this by the inclusion of spectra from the same pigments mixed with different binders (see *PIGMENTS AND BINDERS*).

Organic pigments are more often used in textiles (see *TEXTILES*) and manuscripts; see also ink (see *INK*) (Aceto et al. 2014). Electronic transitions of complex large organic molecules are best described by the molecular orbital theory. Here, not only individual bonds between atoms but also all valence electrons are depicted in combined molecular orbitals, influenced by the combination of all the molecule nuclei. Such electronic transitions between the LUMO and HOMO are depicted in Figure 1d. Especially molecules with a large number of conjugated double bonds will absorb in the visible wavelength range; see also organic dyes (see *DYES*) such as indigo (Tilley 2011).

Cut-off glasses contain inorganic crystalline pigments and are colored by "cutting off" the blue spectral region. The wavelength of the cut-off

depends on the number and size of the crystals. When only the blue spectral region is cut-off the glass appears yellow. When the green is cut-off in addition to the blue, the glass appears orange to red. When the cut-off is shifted further, the glass appears brown and finally black. The absorption is linked to the electronic transitions of electrons between the valence and conduction bands of semiconductor-type crystallites (Figure 1f) (Duffy 1990; Tilley 2011). For such transitions, a minimal radius of only 1.3 nm is required and the band gap shifts with increasing crystallite radius into the visible wavelength region.

Plasmon-resonance absorption of metallic nanoparticles gives silver stained glasses their yellow color, and gold and copper ruby glasses their red color. In metals, positive metal nuclei are embedded in a cloud of negatively charged electrons. When the diameter of the particles is large enough (10–100 nm), these free electrons can be excited in collective oscillations by a beam of irradiation. At the resonance condition, photons of the corresponding energy are absorbed by these nanoparticles (Figure 1e). The absorption by plasmon-resonance depends on the alloys' composition, as well as on the size and shape of the nanoparticles. Scattering effects can be neglected for small particles of less than 50–60 nm in diameter (Tilley 2011).

Mie calculations allow for the simulation of a measured reflectance spectra when the refractive index of the glass matrix and the metal are known. From such calculations, the particle size distribution can be estimated (Tilley 2011). In contrast, opaqueness and opalescence are introduced by scattering particles of larger dimensions. Glasses containing particles (with a diameter d) show opacification by refraction and reflection ($d > \lambda$), by diffraction ($d \approx \lambda$), or by opalescence ($d < \lambda$). Opalescence glasses are often dichroic. Blue, short wavelengths scatter about ten times stronger than the longer red wavelengths. In reflectance, we see the scattered blue light on the glass surface, while the blue is filtered out in transmission and only the red wavelengths transverse through the sample.

The Lycurgus Cup is perhaps the most well-known example of dichroic glass and appears yellowish-red when looking through it and opaque greenish-yellow when looking upon it. The observed attenuation is the sum of scattering by the particles and absorption by

plasmon-resonance; both factors show dissimilar wavelength dependence and, in combination, different colors are observed when the cup is viewed in either reflectance or transmission (Tilley 2011).

For elastic light scattering phenomena, photons interact with matter through a change in direction, but without a change in energy. In the case of inelastic light scattering, both the energy and the direction of the photon are modified. Important examples are Raman scattering and luminescence. Both effects are used extensively in archaeometry (see *ARCHAEOMETRY*). Raman spectroscopy allows the identification of inorganic pigments, while surface-enhanced Raman spectroscopy is employed in conservation (see *RAMAN SPECTROSCOPY IN CONSERVATION*) and on textiles (Ricci et al. 2016). Raman and the complementary method of IR spectroscopy—see also IR absorption (see *INFRARED ABSORPTION SPECTROSCOPY* (IR, FTIR, DRIFT, ATR)) and IR reflectance (see *INFRARED REFLECTANCE SPECTROSCOPY*) spectroscopy—both analyze vibrational modes with energies in the IR wavelength range.

Luminescence is the emission of light after excitation (Tilley 2011). Most common is excitation by photons—see also photoluminescence of Egyptian blue (see *PHOTOLUMINESCENCE OF EGYPTIAN BLUE*) or dating by optically stimulated luminescence (see *DATING AND OPTICALLY STIMULATED LUMINESCENCE*) and optically stimulated luminescence (see *OPTICALLY STIMULATED LUMINESCENCE*). Many polymers such as polyacryl-based glue used in conservation and synthetic paints will show distinct emission spectra. Luminescence can also be triggered by thermal energy—see also dating of ceramics by thermoluminescence (see *DATING CERAMICS AND LUMINESCENCE*) and thermoluminescence (see *THERMOLUMINESCENCE*)—or by IR phonons—see also dating by IR-stimulated luminescence (see *DATING AND INFRARED STIMULATED LUMINESCENCE*).

Optically Stimulated Luminescence

KATERINA THEODORAKOPOULOU

University of Athens, Greece

Since the invention of radiocarbon dating in the 1950s, the arsenal of science-based dating methods has been populated by novel methodologies, pushing our understanding of human evolution further back in time. Science-based dating methods (see *DATING IN ARCHAEOLOGY*) in archaeology take advantage of natural “chronometers” which can be reset by certain biologic, anthropogenic, or other environmental events (Aitken 1998). For example, the radioactive decay of ^{14}C in dead organisms and the progressive racemization of amino acids in collagen are thought of as natural “clocks.”

Among them, luminescence dating methods (i.e., optically stimulated luminescence (OSL) dating (see *DATING AND OPTICALLY STIMULATED LUMINESCENCE*) and its forerunner thermoluminescence (TL) (see *THERMOLUMINESCENCE*)) are of great value in archaeology and the earth sciences. Given that radiocarbon (^{14}C) dating is limited to organic materials no older than 50 kya (Aitken 1998), on the one hand, and the ubiquity of silicate clasts, on the other hand, OSL dating and its long-range dating alternatives is nonpareil.

Luminescence techniques make use of the emission of light from minerals that have been exposed to natural ionizing radiation when undergoing stimulation. When stimulation is carried out by shining light, the light emitted in response is called optically stimulated luminescence (OSL). If stimulation involves heating the sample at high temperatures the emitted light is called thermoluminescence (TL). OSL dating was introduced by Huntley, Godfrey-Smith, and Thewalt (1985). Because OSL is more sensitive to light than TL, OSL is suitable for dating the last exposure of mineral grains to sunlight, known as the *bleaching* event, which corresponds to

the time of deposition. This necessity is met for sediments from archaeological layers.

Grains of minerals that are abundant in sediments, such as quartz and feldspar, memorize their exposure to ionizing radiation: The longer the exposure, the stronger their OSL signal. Natural ionizing radiation is expressed as radioactivity, emitted from decaying isotopes (see *ISOTOPES*) (U, Th, and K) which are ubiquitous in sedimentary environments, and cosmic radiation impinging the Earth's surface from all directions.

Generation of luminescence is associated with the presence of defects in the mineral structure, known as *traps*. In sedimentary deposits the mineral grains are locked from the sunlight, and the intrinsic electronic charge excited by the ionizing radiation may be captured in the traps. Trapped charge accumulates through geological time. In the laboratory under safe lighting conditions (dimmed red light), the accumulated charge can be artificially evicted by stimulating the minerals with special light sources (blue LEDs, for example), and the eviction of trapped electrons will be accompanied by the release of a stream of photons which corresponds to OSL.

The intensity of the OSL signal is dependent on the amount of ionizing radiation the minerals were exposed to, and is measured in *Grays* (Gy). If the dose is divided by the rate at which the dose was delivered (Gy/kya), the time elapsed since the last bleaching event can be estimated. The latter corresponds to the *luminescence age*.

$$\text{Age (kya)} = \frac{\text{Equivalent dose (Gy)}}{\text{Dose rate (Gykya)}} .$$

Sample collection for OSL dating involves the introduction of light-tight (aluminum, PVC) tubes into an excavated (or natural) profile. Sampling is usually carried out in the range of 300–700 g, depending on the nature of the sediment. In cases where the sediment is consolidated, making it difficult to penetrate tubes, we usually extract a block of rock which is then wrapped in opaque wrapper. In cases where the above is impractical, the sample can be excavated

either in daylight under coverage of an opaque tarpaulin and using a dim red light or at night holding a red-light torch and then putting the sample in an opaque bag.

In the laboratory, several separate stages of chemical treatment aim at isolating suitable minerals, such as quartz and feldspar. Sample preparation must be performed in a “dark room,” under red light of low intensity. Initially, the material is processed with hydrochloric acid (HCl) to remove carbonate minerals and calcite cements, and then it goes through hydrogen peroxide (H_2O_2) to get rid of the organic materials. The remaining material is passed through a set of sieves to isolate sand-sized fractions, which typically range between 90 and 180 microns. For sand-sized grains, quartz and feldspar can be separated on the basis of density using heavy liquids: At a heavy-liquid density of 2.62 g cm^{-3} , feldspar floats while quartz sinks to the bottom of a test tube. The mineralogical fractions are then separately etched by hydrofluoric acid (HF) in order to eliminate the outer rind which is nonuniformly irradiated in nature. A final treatment with HCl

is important to remove fluorides during the etching stage. Purified grains are then mounted on approximately 10-mm-diameter stainless-steel or aluminum discs with silicon-spray and are ready for measurement. See Figure 1.

Luminescence readers are instruments designed to conduct signal recordings, heating, artificial irradiations, and OSL stimulations with various light sources: blue diodes, infrared (IR) diodes, green diodes, or IR lasers. Quartz’s luminescence is typically stimulated with blue (470 nm), whereas feldspar is stimulated by IR (870 nm) light. In the case of feldspar, the released luminescence is termed infrared stimulated luminescence (IRSL). Among the two, quartz is considered more appropriate than feldspar, as the latter may suffer from a phenomenon called anomalous fading, which results in age underestimation. The emitted luminescence is detected by a sophisticated unit including a photomultiplier tube and specific detection filters. Artificial irradiations are carried out by a beta-source ($^{90}\text{Sr}/^{90}\text{Y}$) which is attached to the reader and placed in a special protective shielding. The reader

Figure 1 Flowchart showing appropriate procedures for equivalent dose and dose rate determinations to calculate luminescence date.

is automatic and entirely computer-controlled. It can be programmed to execute a sequence of treatments and measurements at the user's will.

Estimation of the natural dose involves the measurement of the natural OSL signal and then its regeneration with successively higher known (regenerated) doses. The OSL signals measured in response (including the natural one) are normalized to the signal of a constant dose (test dose). The resulting plot associating all pairs of dose and OSL signal is called the growth curve, and extrapolation of the normalized signal onto the growth curve defines the laboratory equivalent of the dose termed the *equivalent dose* (D_e) (Figure 2). The above method of D_e evaluation is known as the single aliquot regenerated (SAR) dose protocol (Murray and Wintle 2000). This protocol has the advantage that it enables multiple measurements on individual subsamples (aliquots), allowing the monitoring of the fluctuation of D_e in the sample.

Calculation of the *dose rate* includes the determination of radioisotopes, either by conventional analytical methods, such as neutron activation analysis, or by ICPMS, or techniques based on the release of α -, β -, and γ -rays from the decaying nuclei, such as alpha- and beta-particle counting, or gamma spectroscopy. Radioisotope concentrations are then transformed to dose-rate

units ($\text{Gy} \cdot \text{ka}^{-1}$) which provide the dose rate per radioisotope concentration (ppm).

Accuracy in OSL dating is a serious problem and is case-dependent. Typically, anything less than 10 percent is acceptable. The precision of the average D_e on samples consisting of multiple grains with different burial histories and bleaching is problematic. That is why geochronologists often turn to single grains to acquire better resolution. The oldest age limit of OSL dating is managed by the concentration of luminescence and is defined by the local dose rate, restricting the technique to less than approximately 200 kya. Several methodological and technological developments can extend the age limits further into the Pleistocene (Arnold et al. 2015).

Apart from sediment dating, OSL can also date architectural structures. This can be done by calculating the time passed since the last exposure of a stone's surface to daylight. OSL dating of architectural remains is based on the hypothesis that stone surfaces would receive enough daylight before they were erected. If a sufficient amount of quartz grains can be extracted, then conventional OSL dating protocols could be employed to date the monument.

Figure 2 Growth curve of fluvial quartz from northeast Crete, Greece.

Case studies

Dating archaeological structures

OSL was applied to date extensive prehistoric stone structures in the Black Desert of Jordan in the northern Arabian Desert. When seen from above, these structures appear as geometric lines, which are locally known as the “Works of the Old Men” (Athanasas et al. 2015). Despite their large extent, nothing was known of their chronology. These structures are the result of long-term alteration processes of the desert by the prehistoric inhabitants that resulted in the characteristic landscape of the “Works,” an issue of cooperative work with functional and religious importance. OSL dating was successful in resolving the enigmatic chronology of these structures, showing they were created by a prehistoric culture during the period 8.55–5.42 kya (Late Neolithic–Early Bronze Age).

Dating archaeological sites

OSL was applied to the Middle Paleolithic Blombos Cave in South Africa, with the aim of determining phases of human installation (Jacobs, Wintle, and Duller 2003). The deposits contained significant artifacts, including pieces of engraved ochre, a large number of worked lithics, and bone tools. It has long been known that the majority of the Middle Stone Age (MSA) in South Africa extends beyond the range of radiocarbon dating (~50 kya); therefore, the application of alternative chronological methods, such as OSL dating, was deemed necessary. The ages for the archaeological sediments were obtained from single-grain measurements. An age of 143.2 ± 5.5 kya for the lowermost wind-blown sand deposit of the MSA sequence pointed at oxygen isotope stage (OIS) 6, when the sea level was at about 120 m below the modern sea level. The earliest MSA archaeological phase was found to contain teeth of anatomically modern humans, but most importantly fragments of artistically engraved ochre. This layer was dated to 98.9 ± 4.5 kya, coinciding with the sea level during oxygen isotope substage 5c. The OSL chronology for Blombos Cave not only showed that early human occupation at the site was controlled by global changes in sea level but also demonstrated the earliest known evidence of art.

Dating the paleogeography of archaeological sites

Theodorakopoulou et al. (2012) studied the depositional environment of Istron archaeological site in northeastern Crete, Greece and its sedimentological response to Holocene climatic events. The results of a multidisciplinary geoarchaeological research undertaken in the coastal area of Istron provided information on the depositional environment and the paleoenvironmental and paleogeographic evolution of the area during the Holocene. The identification of the stratigraphy and the distinction of sedimentological units, along with changes of sedimentation rate determined by OSL dating, provided evidence of landscape evolution. Their research also determined the influence of climatic events on the development of archaeological settlement patterns.

Raman Spectroscopy

JOSE LUIS RUVALCABA-SIL and
MARIA ANGÉLICA GARCÍA-BUCIO
Universidad Nacional Autónoma de México, Mexico

Introduction

Archaeological materials provide a unique source of knowledge about human societies in the past, the uses of raw materials, the technology and manufacturing techniques of artifacts, exchange routes and trade, and materials deterioration. It is very important to apply a suitable set and sequence of techniques for characterization of materials, including noninvasive methods such as spectroscopic techniques for in-situ and laboratory analyses, and, depending on the archaeological questions and the kind of studied material, to complete the examination of samples by microanalysis using electron microscopy techniques, molecular and atomic spectroscopies, and chromatography.

Raman is a relatively recent technique for issues related to heritage objects. It has been applied first to the identification of pigments, and its application has been extended to most of the materials of the archaeological record (Edwards and Vandenabeele 2016).

The technique is based on the characteristic energy dispersion of a laser beam after light interaction with the molecules of the material. As a result, a specific spectrum of the material is obtained. Identification of the material can be carried out by comparison with extensive databases of spectra of reference materials and compounds. Depending on the material composition, more than one laser beam is required. The Raman technique is very specific, and can provide chemical and structural information from the same spectrum.

However, some limitations exist due to the low sensibility of the technique and high fluorescence background due to laser interaction with the material. Another important limitation is

the beam damage due to deposited energy at the surface, so the beam intensity must be kept as low as possible, but high enough to obtain a suitable spectrum. This problem depends on each case. To overcome these difficulties, special methods of Raman, such as surface-enhanced Raman spectroscopy (SERS), have been developed, mainly for sample analysis in the laboratory.

Raman instrumentation can be used in the laboratory for microanalysis or in the field using portable equipment for punctual analysis or even surface mapping of objects. This spectroscopy can be successfully applied to inorganic and organic materials and objects from the archaeological record: pigments and paintings, pottery, stone artifacts, gems, glaze, glass, and bone remains.

The Raman effect

The Raman effect has its origin in the electronic polarization of the molecules due to ultraviolet, visible, and near infrared light (Nakamoto 2009). It was reported for the first time in 1928 from the inelastic dispersion of light through a fluid (Raman and Krishnan 1928).

Two processes can occur as a consequence of the light scattering of the molecules. The most likely, the Rayleigh effect, takes place when the scattered photon energy is the same as the incident one. In the second case, the Raman effect, the energy of the scattered photon differs from the incident photon energy. The shift in energy is responsible for the Raman spectra of the molecules. The Raman effect is around one hundred times less probable than the Rayleigh effect.

The vibrational energy levels of a molecule are $E_n = h(n + \frac{1}{2})\nu$, where $n = 0, 1, 2, \dots$; h is the Plank constant; and ν is the frequency of the vibration. When the vibrational transition of the molecule occurs from the ground state ($n = 0$) to the next one ($n = 1$), the energy of the scattered photon is lower than the incident one; this process is known as the Raman Stokes effect. In contrast, the energy of the photon scattered in

Figure 1 Rayleigh scattering: the energy of the scattered photon is equal to the incident one; $E_s = E_i$. Raman Stokes scattering: the energy of the scattered photon is lower than the incident one; $E_s = E_i - \Delta E_{0,1}$. Raman anti-Stokes scattering: the energy of the scattered photon is higher than the incident one; $E_s = E_i + \Delta E_{0,1}$. $\Delta E_{0,1}$ is the difference of the energy between levels $n = 1$ and $n = 0$.

the Raman anti-Stokes effect is higher than the incident photon one (Figure 1).

When a molecule is placed on an external electronic field E , a dipolar moment is induced according to:

$$p = \alpha E \quad (1)$$

where α is the bound polarizability, that is, a measurement of the electronic cloud deformation due to the incident radiation. If the electronic field is regarded as a plane wave, it can be demonstrated that the polarizability takes the form:

$$p = p(\nu_{\text{ext}}) + p(\nu_{\text{ext}} - \nu_v) + p(\nu_{\text{ext}} + \nu_v) \quad (2)$$

where ν_{ext} is the frequency of the incident radiation, and ν_v is the vibrational frequency of the molecule. The first term in equation (2) is the Rayleigh scattering contribution of the polarizability; the second and third are the Raman Stokes and Raman anti-Stokes terms, respectively (Vandenabeele 2013).

According to the Maxwell-Boltzmann distribution, at room temperature, the probability of observing the Raman Stokes effect is higher than the Raman anti-Stokes effect, because the majority of the molecules are in the ground state E_0 .

Instrumentation

A Raman spectrometer consists of a laser source, a system for sample illumination, a device

with a suitable spectral analyzer—which has to be able to disperse all the light according to its wavelength; it could be a monochromator (dispersive instrument) or an interferometer (Fourier transform instrument)—and the detector. The light scattered by the sample reaches the Rayleigh filter (Figure 2) where all the Rayleigh radiation is eliminated using “holographic notch” and dielectric band filters. Raman scattering light passes through a grating which divides the light into its components. The periodic variation of the grating allows it to obtain the spatial resolution of the light according to its wavelength. In the detection, photodiode arrays or charge-coupled devices (CCDs) are often used and each pixel records a different spectral band. A multichannel device is utilized in order to scan the complete spectral range (Larkin 2011). Most common laser wavelengths are 532 and 785 nm; however, 514, 633, and 1064 nm are also utilized. Laser beam spot usually ranges from 1 to 50 μm depending on the system optics; thus, Raman spectroscopy is considered a microanalytical technique.

Recent developments in systems using laser scanners and automatic plates have allowed mapping of the composition of a region of the sample surface or even objects. Also, confocal devices provide a three-dimensional distribution of the compounds of the materials at the surface.

Figure 2 A simple Raman dispersive setup (180° geometry). The microscope permits focusing on the sample surface and directs the scattered light to the spectrometer. M1, M2, and M3 are mirrors and RF is the Rayleigh filter. With SERS enhancement (sample detail (dashed line), laser beam (gray lines)) is amplified by a nanostructure molecule (black line) and reaches the analyte. Raman scattered light of the analyte is amplified repeatedly by other nanostructures (wide black line).

Surface-enhanced Raman spectroscopy (SERS)

Often, the Raman effect is accompanied by a fluorescence interference which hinders the observation of Raman bands in spectra. Fluorescence is the emission of light caused by the relaxation process of a molecule. Another way in which the molecule can lose energy is through the nonradiative process: When a molecule absorbs light, the extra energy is released as thermal energy which is transmitted to the environment.

Success with Raman spectroscopy depends on the material studied. In practice, compounds that contain aromatic rings emit strong fluorescence, such as carbonyl, aliphatic, and alicyclic compounds, and conjugated double-bound structures. For this reason, organic compounds are difficult to be studied by Raman spectroscopy. Nevertheless, many techniques have been developed in order to eliminate the fluorescence background. One of them is SERS, a technique where the Raman signal is amplified and the fluorescence is quenched by the metal nanostructures that are placed very close (some nanometers) to the studied molecule (Aroca 2006). Amplification

of the Raman signal (up to several orders of magnitude) can be explained by two processes: an electromagnetic and a chemical mechanism.

When a metal nanoparticle is radiated with light of a certain wavelength, electrons on the surface begin to oscillate in a collective way in phase with the incident radiation, creating what is known as surface plasmon, and this is the basis of the electromagnetic mechanism. The most common metals used in SERS experiments are gold, silver, copper, and aluminum.

The chemical mechanism consists of the enhancement effect due to charge transfer that happens when a molecule is adsorbed on a nanoparticle surface. Often, a redistribution of electronic cloud in the molecule is responsible for the change in the polarizability, and consequently the enhanced Raman dispersion. Generally, molecular adsorption on a silver surface leads to the formation of Ag–N, Ag–S, or Ag–X (X = halogen) bonds, and it can be observed in the 100 to 300 cm^{-1} spectral region.

For SERS measurements, the sample can be set on a nanostructured support and then irradiated by the beam, or the nanoparticles can be located on the sample surface (Figure 2, detail). Several

SERS methods have been developed for heritage applications (Pozzi and Leona 2016).

SERS has been used to analyze samples in the laboratory. However, in-situ SERS measurements were carried out recently by applying a gel with nanoparticles on a painting surface. After the analyses, the gel was removed with minimum damage to the surface. This approach allows noninvasive and in-situ SERS analyses.

Some applications

New applications of Raman spectroscopy are being developed for archaeological science. Most publications related to archaeology are associated to pigments, pottery, stone artifacts, gems, glaze, glass, and other materials. Often microsampling is required, although in-situ analysis for direct measurement on objects and artifacts has become more and more usual.

Raman spectroscopy is particularly useful for the study of pigments in paintings (on canvas and walls) and documents (Edwards and Vandenberghe 2016). The combination of Raman and X-ray spectroscopies (such as X-ray fluorescence, energy dispersive spectrometry, and X-ray diffraction) has proved to be very appropriate for this purpose. In particular, Raman can be used to test for the presence of specific inorganic or organic pigments. Rock painting pigments in prehistoric contexts as well as ancient world and medieval period wall paintings have been examined by this technique. Blue and green colors that are difficult to identify by other methods can be successfully distinguished because of the fingerprint spectra for indigo, lapis lazuli, azurite, Prussian blue, Egyptian blue, malachite, verdigris, and so on. Similarly, yellow pigments may be clearly distinguished (orpiment, lead-tin yellow I and II, Naples yellow, ocher, jarosite, etc.).

Also dyes (organic color extracted from plants) present characteristic spectra. These pigments are sensitive to environmental conditions; and for this reason usually it is necessary to prepare aged reference materials to obtain suitable spectra to carry out their identification. Recent studies have focused on developing new reference spectra for dyestuffs of Mesoamerica.

In particular, the Raman technique can be used to determine the presence of carbon-based paints and pigments in black colors. This method can be appropriated for the characterization of carbonaceous matter: Crystalline carbon materials present well-defined peaks, while amorphous carbon materials show broad bands between 1300 and 1600 cm^{-1} . Some difference in position, width, and relative intensity can be observed for lampblack, ivory black, bistre, bitumen, graphite, and wood charcoal. These differences can be related to natural or artificial origin and structural implications linked to the use of raw materials or to production processes.

In the case of ceramics, it is possible to study the microstructure by applying the Raman technique to the paste and surface of the sherds and to carry out the identification of crystalline phases corresponding to incompletely transformed raw materials or to new phases formed during firing cycles. This approach provides information about the composition and the thermal processes. It is also valid for glass and glaze in the temperature range 700–1450 °C (from pottery luster to high-temperature fired porcelain glaze). The microanalytical features of Raman spectroscopy make it a powerful and unique method for these purposes.

Textile fibers such as linen, cotton, wool, and silk from the ancient world can be studied using the Raman technique if they are in good conservation condition (Edwards and Chalmers 2005). Archaeological fibers present significant fluorescence due to material degradation. SERS on microsamples is a good option for the characterization of these materials. Aged fiber analysis may help to understand the deterioration process under burial conditions (oxidation, hydrolysis, anoxic environment, and thermal degradation). This information can be obtained from Raman spectra signals related to the polymeric chains and chemical bonds.

Mesoamerican and Chinese jades have also been studied by this method. Jadeite and nephrite are clearly identified and differentiated from other green stone minerals. In particular, the principal Raman band of jadeite, the Si-O-Si symmetrical stretching vibration (703 cm^{-1}), may indicate the proportion of jadeite in the artifacts. This technique has contributed to the study of the exploitation of raw material sources

and exchange routes in Asia and Mesoamerica. Complementary methods for this kind of study are Fourier transform infrared spectroscopy (FTIR), X-ray fluorescence (XRF), and particle induced X-ray emission spectroscopy (PIXE).

Precious stones are materials that can be non-destructively studied by Raman spectroscopy, focusing on gem identification and evaluation of the composition, provenance, and genesis of gems (Bersani and Lottici 2016). In particular, the characterization of mineral inclusions by Raman provides a clue to identify the exploitation of beds of raw materials. Rubies, emeralds, garnets, chalcodites, variscites, and other gems have been studied with this approach.

Reflectometry

NICOLA LUDWIG

State University of Milano, Italy

Reflection and refraction

According to ancient Greek philosophers, human sight was based on a beam of light coming from the eyes, and the picture thus formed of our sensible world was the result of these rays being reflected back by objects and detected by the eyes. In the modern era, this theory has been disproved, because it would require an infinite speed of light to see objects simultaneously at different distances; however, it is a good representation of the way we perceive reality—through reflected signals.

In fact, modern instruments for nondestructive analysis of materials used in a wide array of applications, from the physics of atomic particles to skin cancer detection, work in a similar manner.

From a very generic point of view, reflectometry is concerned with every type of signal coming back from a discontinuity inside a medium (solid, liquid, gas, or mixed) toward which we have sent some kind of energy. In physics, energy is propagated in different ways, such as by energy waves or “kinetic bullets.” Operating in the context of heritage artworks, it is strongly recommended that techniques based on the transfer of kinetic energy, such as a bullet striking a target, should be avoided as far as possible; the bullet’s trajectory could give some information on the structure of the target itself.

In a context where both high penetration of matter and nondestructivity are required, the main choice of researchers will be energy waves. In this domain, two branches can be assumed: The first uses mechanical waves, such as seismic or sound waves; the second uses electromagnetic (EM) waves. EM waves have the incredible property of being able to penetrate and move both

inside matter and in the absolute empty space in the same way, depending only on their frequency and the refractive index of the materials traversed.

The refractive index of a given material (liquid, crystalline, or amorphous) is a measure of how much the speed of light (or other waves such as sound waves) is reduced inside the material. Every time the light (or less specifically an EM wave) encounters a physical interface between two media with different refractive indexes, a reflection occurs. The reflected beam can be detected and measured, giving useful information both on the interface and on the two media.

In reflectance, incident radiation striking a sample can produce two kinds of reflection: diffuse (also called Lambertian) and specular. The radiation that penetrates inside the sample structure interacts with one or more particles and is scattered in all directions (isotropic reflection), and for this reason this component of light is called diffuse reflectance. On a rough or matt surface material, such as textiles (see TEXTILES), pigments, and powders, specular reflected light makes only a very small contribution to the overall signal. In general, every surface has both specular and diffused reflectance (Figure 1).

Diffused reflection contains information on a sample’s compounds and, more specifically, determines its color, whereas in specular reflection each incident ray is symmetrically reflected at the same angle between the incoming beam and the surface normal. It gives information on the source of light and the surface microstructure. In fact, specular reflection is typical of metals, metallic coatings, and glazes (see GLAZES, SLIPS, AND PAINTS). A very useful application of specular reflectance measurements is the study of surface coatings, such as surface-treated metals, paints, and polymers.

Increased path lengths through thin coatings can be achieved using small angles of incidence. Thicker coatings in the micrometer thickness range can be measured using angles of incidence of 30°.

Figure 1 Schema for reflection over a surface. (a) Flat surface (metal), total specular reflection: Ideally the beam is reflected back at the symmetric angle of incident beam. (b) Intermediate case with mixed reflectances. (c) Rough surface (Lambertian reflector): Ideally the whole reflection is diffused isotropically, with no prevalent direction of reflection.

General overview of electromagnetic waves

Different EM radiations interact in different ways with the physical matter of art and archaeological samples.

High-energy rays such as gamma and X-rays penetrate the atom and cause excitation of electrons or nuclear particles, followed by a characteristic reemission (see X-RAY FLUORESCENCE SPECTROMETRY (XRF) and ION BEAM ANALYSIS (PIXE/RBS)). In general, due to the change

of energy of the outward ray, it is unusual to define *reflection* for this kind of high-penetrating radiation.

The same can be said for ultraviolet (UV), which usually causes fluorescence, in which the energy is used to trap electrons in a metastable state and it is then reemitted at lower energy (often in the visible (Vis) range).

On the contrary, in the Vis and near-infrared (NIR) region of the spectrum (380–2500 nm), radiation can interact with structures bigger than a single atom and is reflected back by a multiplicity of different phenomena, such as selective absorption, diffraction (see DIFFRACTION), interference, and scattering.

From a strictly physical point of view, on electromagnetic fields associated with the radiation there is always a process of absorption and reemission, but from a more general point of view, such as in optics, the radiation is reflected, or scattered back, at the same energy level.

Quantitative measurements in the visible part of the EM spectrum (380–780 nm) have great significance for color in the study of heritage objects, through the use of colorimetry. Colorimetry differs from visible spectroscopy (see OPTICAL SPECTROSCOPIES) because it is more connected to the human perception of color.

By taking into consideration the operating conditions of both the observer and the illuminant (i.e., the certified source of light), the values of chromatic coordinates in color spaces can be obtained from the reflectance values of the surface of an object. Different color spaces (RGB, XYZ, Lab, etc.) have been built with the aim of establishing standard color reference naming such that there can be no linguistic misunderstandings. Lab space represents the color space most similar to human perception.

Finally, at higher wavelengths, in mid- and far-infrared (FIR) (see INFRARED REFLECTANCE SPECTROSCOPY) and in the terahertz region, interaction with sample surfaces becomes very complicated in the presence of a large number of absorption energy levels due to the roto-vibrational states of each compound present in the sample and because of black-body radiation. This is the radiation emitted by all objects as a function of their temperature; for room temperature this is centered at 10 microns in the FIR region.

Figure 2 (Left) Schematic representation of a fiber optics reflectance spectrometer (FORS). Light in the long-wave UV, Vis, and NIR is provided by a lamp; through a fiber optic it is focused on a small spot on the sample surface (a few millimeters squared) and then the reflected or backscattered light enters the integrating sphere with almost absolute reflectance whose only exit is the output fiber. This leads the light into a spectrometer where it is dispersed in wavelength with a reflection grating and then projected onto a multiple array detector. (Right) The graph shows a Vis-NIR spectrum of a vermillion sample measured on a fresco in Kobayr church, Republic of Armenia (see Ludwig et al. 2014).

In order to avoid surface reflection, the method of attenuated total reflectance (ATR) (see also INFRARED ABSORPTION SPECTROSCOPY (IR, FTIR, DRIFT, ATR)) has been developed in mid- and far-IR in order to analyze the compounds of the sample instead of characterizing optically (external reflectance).

Nonionizing radiations (short-penetrating radiation)

Reflectance spectroscopy or spectral reflectometry (SR) is a method of characterizing the optical properties of samples by measuring the reflection of EM radiation coming from an object. In most implementations the wavelength ranges from weak UV to NIR, 200–2500 nm.

With this method, light is shone upon the sample, and this interaction with the sample causes some light to be scattered back—or reflected (hence the name “reflectometry”). The reflected light can be measured by placing detectors along the path of the reflected light. Light is further separated into its wavelength components, and eventually into its various polarization directions (*ellipsometry*).

Figure 2 shows a schematic of a basic system for SR using fiber optics (Bacci 2000). Light, in the

long-wave UV, Vis, and NIR regions, is provided by a multispectral lamp (often halogen plus a deuterium bulb); then through a fiber optic the light is focused on a small area of only a few millimeters squared on the sample surface.

The backscattered (reflected) light enters the integrating sphere with almost absolute reflectance where the only exit point is the output fiber. This fiber leads the light into a spectrometer where diffraction occurs (in general with a reflection grating) and it is then projected onto a multiple array detector.

Both the number of detectors and the width of the light beam determine the spectral resolution of the spectrum. In Figure 2 (right) the actual resolution of the spectrum is only 2.7 nm, whereas the number of detectors is 3,600 over a range of about 900 nm.

In applied spectroscopy, the relationship between the amount of light reflected (diffuse reflectance) and the absorption and scattering properties of a given material was formulated in the 1940s by Kubelka and Munk (Hunt, Gainer, and Pointer 2011):

$$\frac{K}{S} = \frac{(1 - R_{inf})^2}{2R_{inf}}$$

where R_{inf} represents the reflectance of an infinitely thick sample of the material (actually a

few millimeters or less). S and K are scattering and absorption spectral (i.e., wavelength-dependent) coefficients, respectively. They represent the property of the compounds to absorb or reemit the radiation after it has hit the minute particle of pigment or light-diffusing material.

By using a spectra database of similar materials, for example a set of painted pigments (see CHARACTERIZATION OF PIGMENTS) or dye (see DYES), in the same given range of wavelengths, the composition of paint can be deduced, and also what its spectrum looks like in terms of the absolute and relative maxima and minima of the curve.

The reflectance graph displayed in Figure 2 (right) shows the spectra in the Vis-NIR range of a sample of vermillion found in the fourteenth-century fresco in Kobayr church in Armenia (Ludwig et al. 2014). This brilliant red pigment was widely used in the ancient world and it was obtained from cinnabar, a mineral composed of mercuric sulfide (HgS). This kind of spectrum is described as “S-shaped” for its characteristic three-step trend: low value—sharp climb—plateau of high constant reflectance. This reflectance spectrum and therefore its absorbance are characterized by a trend typical of semiconductor materials in which energy is absorbed only from a threshold value.

This behavior is due to the peculiar electronic transition that can be found in pigments such as *minium*, *cadmium yellow*, *cadmium red*, and *orpiment*. The *energy band transition* occurs when all the molecular orbitals of the atoms are close enough to each other that the orbitals become a continuum over all of the crystal, namely energy bands (Bacci 2000). In semiconductors, there are two bands of the named pigments: one filled with electrons and the other empty, separated by an energy gap. When the energy of the incoming radiation is higher than this characteristic gap, the electrons in the full band absorb it in order to empty the band. When the energy of the radiation is lower, it is scattered away. This threshold value determines the typical shape of the spectra of that kind of material, making them easily recognizable.

The absorption spectrum gives the step transition between absorbed and nonabsorbed energies. Spectra with peaks—or more properly bell-shaped sections—are characteristic of the electronic transition between isolated molecular

orbitals. Even more characteristic bands in reflectance spectra can be found, typically in colored glass (see GLASS COLOR), where the color is due to the presence of very low concentrations of the transition metal and the glass itself can be considered as transparent (Fermo et al. 2016).

Other bands of EM radiation, in particular mid- and far-IR (2.5–25 μm), are widely used to identify chemical compounds, thanks to the characteristic, very complex set of absorbance peaks (fingerprint) due to the rotational and vibrational modes (see VIBRATIONAL SPECTROSCOPIES) of both organic and inorganic molecules. This spectroscopy (Fourier transform infrared spectroscopy (FTIR)), however, works in the absorbance spectrum more than in the reflectance spectrum; the signal reflected back is of little interest compared to the signal transmitted through a sample, and therefore FTIR is no longer considered to be a reflectometry technique at all (Khoshhesab 2012). Furthermore, in reflectance mode the sample must be milled and mixed with a nonabsorbing matrix such as KBr to ensure deeper penetration of the incident beam into the sample, in order to increase the contribution of the multi-scattered component. However, the technique cannot be considered as noninvasive and therefore it is not so appropriate for analyzing paintings and delicate works of art.

Recently, devices have been developed for FTIR working over 2.5 μm , which are able to operate in an experimental reflectance set-up with totally contactless measurements and therefore can obtain absorbance peaks as values that are complementary to the reflectance spectra measured.

Finally, it is important to emphasize that in totally contactless applications, such as on frescos or easel paintings, the output spectra can be strongly influenced by gypsum, glue, and the pigments of the painting background (“*preparazione*”) (Bacci 2000). This is due to the higher penetration of IR radiation inside pictorial layers.

Ultra-penetrating radiations (terahertz)

Terahertz reflectometry (see TERAHERTZ IMAGING IN CONSERVATION), using radiation of

some tenths of a millimeter of wavelength, may be used for noninvasive measurement of the thickness of a paint layer (Dandolo, Koch, and Jepsen 2016) as well as for estimation of pigment particle sizes. This aim can be achieved using a scanner over the painted surface. Every discontinuity along the transmission path within the material causes a part of the original signal to be sent back. Monitoring these reflections over time, it is possible to detect structural defects such as delaminations and to distinguish inner structures clearly. However, despite the potentially great penetration of this longer-wave radiation (see GROUND-PENETRATING RADAR and RADAR), terahertz is not yet widely applied in the analysis of art and archaeological objects.

Mechanical reflection (acoustic, ultrasound, and neutrons)

Acoustic waves are another important means of penetrating matter. They do not need an electromagnetic field and are not perturbed by any electromagnetic property of the atoms on their path. In ultrasound, an emitting antenna generates waves that enter the object (usually stone). The wave can be partially reflected every time it reaches an interface inside the propagation medium (for example, a crack or an inclusion of different materials). The waves reflected back to the receiving antenna, the time taken to reach it, and the amplitude of the waves give the impedance of the material and the depth of the crack.

Acoustic waves (20 Hz–200 kHz) have been recently applied in the investigation of heritage materials such as pictorial layers on frescoes, ceramics, or detachments in easel paintings. The acoustic energy absorption diagnostic device (ACEADD) produces diagnostic images using an acoustic source (kHz) with spatial resolution, useful in the restoration and conservation study of artworks (Maev, Green, and Siddiolo 2006). A chirp signal of a combined high-frequency set of acoustic waves can be selected to excite the possible delaminations of painting layers, cutting off the lower frequencies characteristic of the vibration of the massive wood substrate.

Neutron reflectometry (NR) uses neutrons' scattered angles to probe the nuclear composition and magnetic properties of materials characterized by a flat surface (see NEUTRON IMAGING AND TOMOGRAPHY IN CONSERVATION). The detection of the intensity of reflected particles as a function of angle or neutron wavelength gives spectra of reflectivity whose shapes provide information about how the surface is made, including thickness, density, and roughness of any thin films possibly layered on the substrate. The strong interaction of neutrons with hydrogen and deuterons enhances its capability to study mineral compounds characterized by such elements. NR has proved to be useful for studying stone, glass, and ceramic as well as painted surfaces.

Institute of Applied Statistics and Computing, Austria

The microscopic and material analysis of heritage materials has a history almost as long as technical microscopy and analytical chemistry themselves. Martin Heinrich Klaproth (1743–1817), who discovered the elements chromium, uranium, zirconium, and titanium and became the first professor of chemistry at the University of Berlin in 1810, had published results about the chemical composition of ancient glass, Greek and Roman bronzes, and coins already around 1800 (Klaproth 1792). Klaproth had to use the chemical techniques of gravimetric analysis and developed new chemical recipes for the separation of copper, lead, and tin for their quantitative determination. Thus large amounts of sample material or even smaller coins had to be dissolved in nitric acid (HNO_3), a procedure that cannot be accepted by archaeologists, curators, or conservators nowadays.

A big change in the material determination and description of archaeological finds, and also artworks, occurred at the beginning of the last century, when physicists and analytical chemists developed the electron microscope (Ruska and Knoll 1931) and microchemical spot tests (Feigl 1954a, 1954b) for which only a few micrograms of material are required. Such investigations were widely accepted and applied in the archaeological sciences, as these tests enable the identification of inorganic as well as organic materials in a first survey. However, for each spot test original sample material had to be taken, which can be a limiting factor in many cases, and only the

presence or absence of a specific element or chemical group is revealed.

After World War II a great number of so-called instrumental techniques for microscopic and material analytical investigations could be developed. Their key benefit, if we compare them to chemical spot tests as well as to optical microscopy, is the simultaneous detection of all or most chemical elements present in or on an object. Furthermore, rapid improvement during the last decades, especially in the area of microelectronics and computer sciences, has led to a great variety of nondestructive or even noninvasive microscopic and analytical techniques.

A word about the terms “nondestructive” and “noninvasive” might be appropriate at this point. For an archaeologist, art historian, or conservator, these terms are identical with “nonsampling.” Furthermore, no changes and alterations must occur or are necessary before, during, or after the analyses. In contrast to that, for the analyst, the terms have the connotation that a specimen of an object, for example, is preserved during the analytical procedure. In that sense the methods of electron microscopy can be seen as nondestructive techniques; and small objects or fragments of archaeological finds that fit into the sample chamber of the instrument can be studied, since, owing to the absorption of electrons in air, the investigations usually have to be carried out under vacuum.

Principles of scanning electron microscopy and electron probe X-ray microanalysis (EPXMA or SEM/EDX, SEM/WDX)

The invention and construction of the electron microscope by Knoll and Ruska (1932) and of the electron microprobe (EMP) by Castaing in the middle of the last century (1951) had an enormous impact on all fields of materials science. Only a decade later, Hornblower (1963) and Ogilvie (1970) suggested the EMP for various applications in archaeometric studies. The EMP combines the possibilities of simultaneous

Figure 1 Signals in the scanning electron microscope caused by elastic and inelastic interactions of an incident electron beam with sample matter. On the left-hand side the corresponding information depths of the signals are given with approximation, as these depend on the composition and structure of the material.

Source: Schmidt, Balk, and Blaschke 2004.

imaging and analysis of the microdomains of an archaeological object or sample (Reimer 1985; Reed 1993). Its principle is based on the interaction of a finely focused electron beam emitted by a heated tungsten wire, and the subsequent detection of various emerging signals produced by elastic and inelastic processes in the material (Figure 1).

Measurements of the backscattered electrons (BE) as a function of the position of the electron beam scanning over a predefined area on the sample surface yield an image depicting contrasts between regions dominated by low-Z elements and regions of high-Z elements (so-called “material contrast”; Z refers to the atomic number). Hence the BE image allows for instance the characterization of inhomogeneities (depletions or enrichments of certain elements) at the core or in the surface domains of weathered or corroded materials such as metals (see CHARACTERIZATION OF METALS AND ALLOYS) or glasses (see GLASS AND FAIENCE).

Secondary electrons (SE) are the result of inelastic scattering processes in the sample material that cause for example ionization of electronic

states of the sample atoms. When collected with a secondary electron detector, these secondary electrons originating from the outmost surface layers of the specimen can be used for topographical and morphological imaging of the sample surface—just like a light microscope, but with a much better lateral resolution (approximately 3 nm compared to 1 μm). In the case of (historical) materials, SE images are widely used for characterizing the morphology of their weathered or corroded (and therefore often rough) surfaces.

The interaction of incident primary electrons with sample matter also causes ionization of the inner shells of sample atoms, which results in the emission of characteristic X-rays. As in X-ray fluorescence analysis (XRF; see X-RAY FLUORESCENCE SPECTROMETRY (XRF)), this X-ray radiation can be detected, yielding a characteristic spectrum of the whole sample or enabling rapid qualitative and quantitative analysis of major, minor, and trace components from selected microdomains.

The principle of X-ray microanalysis is based on the photoelectronic absorption process and can best be demonstrated using Bohr’s atomic

Figure 2 Principle of XRF: The incident X-ray photon (I) causes the ionization of an inner shell (e.g., the K-shell, II). The subsequent relaxation process leads to the emission of X-ray radiation (III) characteristic of the element.

Source: Jenkins 1999.

model (Figure 2): the primary electrons cause the ionization of inner-shell electrons of the material. A vacancy in an inner shell means a highly excited state, and the atoms return to a more stable electronic configuration by emitting X-ray photons ("characteristic" or "element-specific" X-rays) or Auger electrons (not considered here) according to certain quantum-mechanical rules. The specific X-ray photons can be detected in two fundamentally different ways: by a crystal spectrometer, according to their wavelengths ("wavelength-dispersive," WD); or by semiconductor detectors ("energy-dispersive," ED). The major benefit of the latter is the shorter measuring time (typically 50 s), whereas its most significant drawbacks are a lower resolution (typically 130–50 eV) and an inferior detection limit by comparison to the wavelength-dispersive detection mode. As the detected X-rays are characteristic of certain elements, qualitative analysis is straightforward in most cases, while quantitative analysis generally requires either standard materials of known composition and the application of numerical procedures (the so-called "ZAF corrections") or an extensive mathematical treatment of the raw data (the fundamental parameters method).

Measurements in a scanning electron microscope, in combination with either EDX or WDX detection, are in principle nondestructive but, owing to the high absorption of the electrons in air, such instruments have to be operated in vacuum (typically 10^{-5} mbar). As the sample chamber has a limited volume, only small objects like coins or glass fragments can

be analyzed without taking a specimen. In most cases sampling will be required; furthermore, the application of this technique might not be suitable for vacuum-sensitive specimens such as organic or even inorganic materials, for example corroded or weathered glasses, as outgassing of incorporated water may occur. Additionally, thin layers of carbon or gold (typical thickness of 50 nm) have to be sputtered on the sample surface prior to the measurements in order to avoid charging of the specimen when bombarded with electrons. These drawbacks can partly be avoided by using an environmental scanning electron microscope (ESEM) developed in the 1980s, which allows investigations under H_2O vapor atmosphere (pressure approximately 1 Torr) in the sample chamber, while maintaining high vacuum conditions in the microscope column.

The theoretical detection limits of SEM/EDX and SEM/WDX are in the range of 0.1 and 0.01 weight percent (wt.%) respectively, and hence the methods are primarily suited for analyzing major and minor components. In principle, all elements with atomic numbers $Z \geq 3$ (lithium, Li) can be analyzed, but in practice elements with $Z \geq 5$ (boron, B) can be detected depending on the detector technology used. In any case, the electron dose applied onto the specimen should also be kept as low as possible, since numerous recent studies showed more or less severe structural and compositional changes, for example in glass, caused by the incident electron beam.

In summary, SEM/EDX investigations give a clear answer concerning the qualitative and quantitative elemental composition of the bulk

material as well as of the degraded surfaces. Furthermore, the chemical composition and the morphology of corrosion and weathering products yield valuable information on the authenticity of the patina, for instance, and hence on the provenance of a finding. It is therefore not surprising that a close collaboration between archaeological and natural sciences has developed in the last decades. Concerning a series of archaeological findings, the question arises whether these objects exhibit some kind of “characteristic composition,” which can further be used to assign “unknown” objects to a certain place or time of manufacture (in addition to the visual and stylistic analysis), to allocate an object to a particular historical or archaeological context (evidence of trading), to determine the correctness or incorrectness of the claimed provenance, or to explore the technology of manufacturing. The base is therefore to determine when new materials, techniques, or technologies have been introduced or others came out of use. However, the analysis of a great number of dated or precisely datable artifacts is necessary and enables us to set up a *terminus post quem* or a *terminus ante quem* for pigments, metal alloys, or glasses, for example, and also for methods developed or even invented for materials processing or fabrication.

Regardless of the analytical method employed for a given problem, a scientist working in the field of archaeology is often confronted with a huge amount of data, particularly if spectroscopic methods are applied. Therefore the application of suitable multivariate statistical procedures is of particular importance for understanding certain relations in the data. The most frequently applied methods in the field of chemometrics are principal component analysis (PCA), factor analysis (FA), and cluster analysis (CA), which often allow for the identification of (sub)groups of similar objects or outlying observations. These and many more methods are implemented in most commercial or freeware statistical software packages, for example SPSS (SPSS Inc.), SAS (SAS Institute Inc.), or R (Freeware).

Analytical investigations have become an important part in the interdisciplinary cooperation of heritage studies, if the specific technique can be applied to an archaeological object in a nondestructive or even noninvasive way. Among the large variety of modern methods available in

materials science characterization, SEM/EDX has certainly a prevalent place.

Sequencing DNA

TERENCE A. BROWN
University of Manchester, UK

DNA sequencing is the process by which the order of nucleotides in a DNA molecule is read. Deoxyribonucleic acid (DNA) has a polymeric structure comprising monomers called nucleotides. There are four nucleotides, whose chemical names are abbreviated to A, C, G, and T. These four nucleotides can be linked in any order in linear polymers (“polynucleotides”) millions of nucleotides in length. The order of the nucleotides in a polynucleotide constitutes the DNA sequence. The length of a DNA sequence is measured in base pairs (bp), with 1 bp being a single nucleotide, 1 kilobase pair (kb) being 1,000 bp, and 1 megabase pair (Mb) being 1,000 kb.

A DNA sequence can provide three different types of information relevant to archaeological research. First, a DNA sequence is characteristic of the species of origin and can be used to identify that species. This enables unidentified bone fragments to be characterized, but is more valuable as a means of assessing the disease status of a human skeleton, by identifying the preserved remains of microbial pathogens present in a bone or tooth. Second, those components of the sequence called genes specify the biological characteristics of an individual, which means that DNA sequencing can be used to distinguish males and females, and to provide information on characteristics such as hair color and disease susceptibility. Third, the DNA of an individual, being inherited through generations of parents, grandparents, and so on, provides a record of ancestry. DNA sequencing can therefore reveal the kinship relationships between individuals, and enables individuals to be placed into population groups.

DNA sequencing methodology

The first efficient methods for DNA sequencing were developed in the mid-1970s. One of these, chain-termination sequencing (Sanger, Nicklen, and Coulson 1977), became popular because of its ease of use, reliance on nonhazardous chemicals, and ability to be formatted into automated systems. Virtually all DNA sequencing projects between 1980 and 2005 made use of this method, including the Human Genome Project, which was completed in 2000.

The chain-termination method employs a DNA copying reaction that is carried out in the test tube, driven by a purified DNA polymerase, the type of enzyme that performs DNA synthesis in living cells. A new DNA molecule is synthesized, the sequence of this new “chain” dictated by the sequence of the molecule being copied, the latter referred to as the template. A natural pairing process ensures that an A nucleotide in the template is copied into a T in the DNA that is being made, a C is copied into a G, a G into a C, and a T into an A. The test-tube reaction is performed with a mixture of standard and modified nucleotides, the latter blocking further DNA synthesis and hence causing chain termination. There are four modified nucleotides, called ddA, ddC, ddG, and ddT, each of these labeled with a different fluorescent marker. Each of the new DNA molecules that is synthesized therefore becomes terminated with a modified nucleotide whose identity indicates the identity of the nucleotide in the template at the termination position. The sequencing experiment is designed so that all the DNA molecules that are made begin at the same position on the template DNA. This means that the sequence of the template from that position can be read by placing the chain-terminated molecules in length order, and identifying the terminating nucleotide carried by each one. Separation by length can be achieved by polyacrylamide gel electrophoresis, and the

terminating nucleotide on each molecule can be identified from its fluorescent label. The sequence of the template is therefore read by electrophoresis of the chain-terminated DNA molecules past a fluorescent detector.

The chemical reaction underlying synthesis of a new DNA molecule does not have infinite capacity and the maximum length of sequence that can be read by a single chain-termination experiment is 800 bp. This is not a major problem when ancient DNA (aDNA) from archaeological samples is being studied, because the natural diagenetic processes mean that preserved DNA molecules are highly fragmented derivatives of the original chromosomal molecules, and are rarely longer than 200 bp. The weakness with chain-termination sequencing is the need to purify from the complex mixture of DNA molecules in a sample just those fragments covering the short region of interest, these fragments acting as the templates for the sequencing experiment. With aDNA, this purification step is almost always performed using the polymerase chain reaction (PCR), which results in the repeated copying of a pre-specified DNA segment. The region of interest is therefore amplified from the starting sample by PCR, and the resulting DNA copies used as templates in the DNA sequencing experiment. This approach has two drawbacks. First, a different PCR and chain-termination experiment must be set up for each short (<800 bp) DNA sequence that is sought. The approach is therefore labor-intensive and requires relatively large amounts of starting material in the form of, for example, a bone or tooth extract. Second, copying by PCR is prone to contamination, as minuscule amounts of modern DNA, such as can be deposited on an archaeological sample by handling, will be amplified preferentially compared with the chemically degraded aDNA component of the sample. Despite the use of controls and rigorous technical regimes, the possibility that “aDNA” sequences obtained by PCR and chain-termination sequencing in fact derive from modern contamination can never be entirely excluded.

In genomics research, the desire to obtain complete genome sequences cheaply and rapidly has led to development of new sequencing methods that can provide much greater quantities of data than the chain-termination technique. The first

of these “next generation” methods appeared in the mid-2000s and additional technologies have been introduced regularly since then (Goodwin, McPherson, and McCombie 2016). All of these methods follow the same underlying procedure. The total DNA content of the sample is broken into fragments of approximately 200 bp and the fragments immobilized as individual units on a solid support in an array format. All of the fragments are then sequenced in parallel. The various technologies that are available employ different techniques for the sequencing step, but most are based on synthesis of a copy of each immobilized fragment, the order of nucleotides incorporated into this copy being read as the reaction progresses. For example, the procedure referred to as Illumina sequencing makes use of fluorescently labeled nucleotides, with each addition to the DNA molecule that is being synthesized identified by detection of the label carried by that nucleotide. Other approaches, such as the ion torrent and pyrosequencing methods, do not directly detect the nucleotide addition but instead detect the release of hydrogen atoms and phosphate molecule, respectively, that accompanies each nucleotide addition. Nucleotides are therefore applied one after the other in a repetitive series (e.g., A, followed by C, followed by G, followed by T, followed by A, etc.). If a nucleotide is unincorporated, then it is washed away and replaced with the next in the series. When the correct nucleotide is applied, and added to the end of the molecule being synthesized, the hydrogen or phosphate release is detected. The step-by-step addition of nucleotides to the growing DNA chain can therefore be followed, enabling the sequence of the template molecule to be read.

Regardless of the detailed methodology, the outcome of a next generation experiment is a dataset of millions of short sequence reads, representing all of the DNA fragments in the original sample. Analyzing such vast amounts of data presents a computational challenge, but the importance of sequencing in genomics research means that considerable effort has been put into development of bioinformatics pipelines for the reconstruction of complete genome sequences from next generation reads, or alternatively for identification of reads representing genes or other DNA regions of interest. These pipelines

are readily transferable to aDNA projects. The use of a next generation method does not entirely solve the problems that arise if an archaeological sample is contaminated with modern DNA, and a rigorous technical regime must still be followed to prevent contamination. The advantage of next generation sequencing in this regard is that the vast amount of sequence data makes possible a statistical approach, based on analysis of individual reads for sequencing errors that signal the presence of nucleotide breakdown products resulting from diagenesis, enabling a post-hoc assessment of the likelihood that the reads are authentic aDNA.

DNA sequencing applications in archaeological science

Whether using the chain-termination method or a next generation approach, the applications of DNA sequencing in archaeology are dependent on aDNA actually being preserved in the samples under study. Surprisingly few attempts have been made to understand the diagenetic processes responsible for DNA breakdown in any type of biological material, most of the information coming from observation of DNA presence or absence in materials of different types and ages, rather than from a predictive approach based on measured rates of DNA decay. These observations suggest that aDNA can be sequenced from bones and teeth up to one million years in age, but for this age to be reached the samples must be preserved under relatively cold and/or dry conditions. Under temperate and moist conditions, the DNA content of a bone can decline rapidly over a period of a few centuries or even decades. It is also clear that DNA decay in bones accelerates after excavation, possibly because removal from the burial environment and re-exposure to air leads to a resurgence of microbial activity within the bone. Natural and artificial mummies, as well as explants such as hair, have also yielded DNA sequences, but these types of material have been less extensively studied and the time limits for DNA preservation are unknown. Desiccated plant remains up to several thousand years in age can contain relatively well-preserved aDNA, but charred remains are poor sources, because of the

rapid DNA breakdown that occurs at the temperatures associated with the charring process.

Despite the challenges resulting from the unpredictable preservation of aDNA and the possibility of contamination, DNA sequencing has had a remarkable impact on archaeological research since the late 1980s when the survival of DNA in bone was first demonstrated. This impact has encompassed areas of archaeological endeavor from interpretation of individual sites to broad hypotheses regarding biological and cultural evolution. At the level of individual site interpretation, DNA sequencing has been used extensively in sex identification of skeletons for which conventional typing by osteological methods is not possible. This approach has been particularly informative with infant and neonate skeletons, which have no sex-specific osteological distinctions, and has enabled hypotheses regarding infanticide to be tested. For example, 12 of 35 infant burials from a Roman-British villa at Hambledon, UK, were typed in this way, seven of the infants being shown to be female and five male (Abu-Mandil Hassan et al. 2014). This unskewed ratio suggested that, contrary to previous reports, sex-specific infanticide was not being practiced at this site. With these samples, DNA sequencing was also carried out with segments of the mitochondrial DNA of the infants, enabling maternal relationships to be assessed. No two infants had the same mitochondrial sequence, indicating that each was the child of a different mother. Again, this information helped to dispel previous interpretations of the site as a Roman brothel.

DNA sequencing has also been used to confirm and extend the paleopathological examination of human remains. This approach has been most successful with tuberculosis (TB). Although mainly a disease of the pulmonary system, 3–5 percent of those individuals who become infected with TB progress to an osteological stage, during which *Mycobacterium tuberculosis* bacteria spread via the blood and lymphatic systems to the bones, sometimes resulting in lesions to the thoracic and/or lumbar vertebrae and possibly destruction of the joint surfaces of the knees and hips. None of these changes is diagnostic of TB and, though indicative, they do not constitute proof of infection. The vast majority of cases that display only the pulmonary form of the disease present no osteological indicators, other than

occasional new bone formation on the visceral surfaces of ribs, which is associated with various types of pulmonary infection and again is not diagnostic for TB. Greater precision in the diagnosis of TB has been achieved by sequencing, which has identified *M. tuberculosis* DNA in extracts from skeletons displaying TB lesions and also from skeletons with no indicators of the disease (Donoghue et al. 2015). This work has progressed to the stage where it is possible to use DNA sequencing to distinguish between different subtypes of the bacterium, enabling direct examination of the evolution of the disease over the last 2,000 years (Müller, Roberts, and Brown 2015). There have been similar successes in sequencing plague bacilli from human remains and in confirming osteological detections of leprosy, but the DNA sequencing approach to paleopathology is not unlimited in scope. To use sequencing to detect a pathogen, the DNA of that pathogen must be present in the bones or teeth at the time of death, or must find its way into the skeleton by absorption from, for example, the bone marrow. This is not the case with all diseases, as with many infections the pathogen load can be quite small at the time of death, or might be restricted to the stomach or intestines, resulting in very little pathogen DNA being preserved in the skeleton.

Sequencing of DNA from plant remains has revealed aspects of the evolution of domesticated crops, especially with maize, which is amenable in this regard because of the availability of desiccated remains from various sites in the Americas (Jaenicke-Després et al. 2003). However, the most interesting discoveries have come from analysis of barley and other Old World crops preserved at Qasr Ibrim on the upper Nile. This site was occupied for 3,000 years until a few hundred years ago, and remains of crops grown at the site have been recovered from several excavation levels. DNA sequencing of these remains has revealed genetic adaptations that enabled these plants to be cultivated in the hot and arid conditions present at the site (Smith et al. 2017). The information obtained by these studies is interesting with regards to the development and maintenance of sustainable agriculture at Qasr Ibrim, and is also relevant to the efforts of plant biologists to breed new varieties of crops better able to resist modern climate change.

Returning to the sequencing of human DNA, the area of research that has had the most broad-ranging impact on both archaeological and human evolutionary studies has been the assembly of complete genome sequences for extinct hominins and prehistoric examples of *H. sapiens* (Llamas, Willerslev, and Orlando 2017). The first Neanderthal genome sequence, published in 2010, was a composite of three 38,000-year-old samples from a cave in Vindija, Croatia. This was followed by a more accurate sequence from a single individual of approximately 50,000 years from Denisova Cave in the Altai Mountains, Siberia. This cave also contained other bone fragments and teeth that initially yielded a mitochondrial DNA sequence that was so different from those of Neanderthals and modern humans as to suggest a new species, although subsequent sequencing of the nuclear genome identified these “Denisovans” as a sister group of Neanderthals. Comparisons between the Neanderthal, Denisovan, and *H. sapiens* genomes have revealed that these three types of hominin interbred, with some 2.0 percent of the modern European genome obtained from Neanderthals, and the modern Asian and Oceania human genomes similarly influenced by introgression of DNA from Denisovans. One of the more intriguing discoveries of recent years has been the presence in Tibetans and some other Asians of a variant of the EPAS1 gene, which is absent in other modern human populations but was present in Denisovans, and which is thought to have been obtained by the Asian groups from that source. The specific role of the EPAS1 gene is in the response of humans to low oxygen environments, the variant present in Tibetans providing enhanced tolerance to the reduced oxygen levels at high altitudes. The ability of humans to colonize the high mountainous regions of the Himalayas may therefore be due to past interbreeding with Denisovans.

Spectroscopy

IVANA ANGELINI

Università degli Studi di Padova, Italy

We generally define spectroscopic processes as all interactions of radiation with matter involving a quantized exchange in energy. In more general terms, because of the De Broglie concept of wave-particle duality, the incident probe on the analyzed material may be electromagnetic radiation (described as waves or photons) or particles (electrons, neutrons, protons). In all instances, we consider the transfer of energy quanta from the probing beam to the electrons or the nuclei of the investigated atoms (Calas and Hawthorne, in Hawthorne 1988). The photon energy due to an electron transition between an upper atomic level k (of energy E_k) and a lower level of energy E_i is:

$$\Delta E = E_k - E_i = h\nu = hc\sigma = hc/\lambda_{\text{vac}}$$

where ν is the frequency, σ the wavenumber in vacuum, and λ_{vac} the wavelength in vacuum (Atkins, de Paula, and Keeler 2017). The energy exchange is commonly treated in terms of *absorption* or *emission*. Rigorously, spectroscopy deals with the description and quantification of the excitation processes, whereas spectrometry is involved with the instrumental measurement of the absorbed or emitted signals. The two terms, however, are often used interchangeably.

During the absorption process there is a transfer of energy from the incident beam to the atoms in the material, and consequently the excitation of the electrons or the nuclei particles from the ground state to an excited state. The change in energy level is defined as a transition between states. We measure the frequency and the magnitude of the absorbed radiation in order to obtain specific information on the energy levels of the atoms to be investigated. The energy of the probe determines which energy levels are excited: As a first approximation, γ -rays excite nuclear levels, high-energy X-rays excite core

electrons, soft X-rays excite outer electrons, ultraviolet (UV) and visible radiations excite valence electrons, and infrared (IR) radiation excites molecular vibrations and phonon waves. The experimental techniques measuring the energy dependence of the absorption of radiation from matter are called *absorption spectroscopies*. Experimental techniques of this kind are, for example, atomic absorption spectroscopy, IR absorption spectroscopy (see INFRARED ABSORPTION SPECTROSCOPY (IR, FTIR, DRIFT, ATR)), and X-ray absorption spectroscopy (see X-RAY ABSORPTION SPECTROSCOPY (XAS, EXAFS, XANES)).

The emission of radiation from the atoms upon decay from the excited state to the ground state (often involving transitions to intermediate energy levels) is also a powerful source of information on the intrinsic energy states of the atoms in the material. This is due to the coupling of the absorbed radiation to internal atomic processes, which causes reemission of radiation having different frequency. The frequency shift and the intensity of the emitted radiation are related to the chemical nature and environment of the atoms and are measured by a number of *emission spectroscopies*. Experimental techniques based on the measurement of emitted radiation are, for example, Raman spectroscopy (see RAMAN SPECTROSCOPY), X-ray fluorescence (XRF) spectroscopy (see X-RAY FLUORESCENCE SPECTROMETRY (XRF)), laser-induced breakdown spectroscopy (LIBS) (see LASER-INDUCED BREAKDOWN SPECTROSCOPY (LIBS)), and optical emission spectroscopy (OMS). Much like in absorption spectroscopies, different information concerning the atoms is obtained depending on the energy of the emitted radiation: γ -rays yield information on the nature and state of the nuclei (such as in Mössbauer spectroscopy (see MÖSSBAUER SPECTROSCOPY)); hard X-rays emitted from the ionization of core electrons yield information on the electronic structure, and thus on the chemical composition (such as in XRF and portable XRF (pXRF); see PORTABLE X-RAY FLUORESCENCE SPECTROMETRY (PXRF)); and soft X-rays yield information on the valence of

DOI: 10.1002/9781119188230.saseas0546

atomic species (such as in X-ray photon electron spectroscopy (XPS)). The emission of characteristic visible radiation from outer electronic levels may yield chemical information by OES or LIBS, whereas Raman scattering (see RAMAN SPECTROSCOPY) probes molecular vibrations and phonon waves in solids and may usefully be employed to identify molecules and inorganic compounds.

Only the most diffused spectroscopic techniques are treated in the *Encyclopedia*; nonetheless, it should be appreciated that spectroscopic concepts and experiments are fundamental to any analytical approach to archaeological materials.

Thermoluminescence

M. MARTINI and E. SIBILIA

Università degli Studi di Milano Bicocca, Italy;
MIB-INFN, Italy

Thermally stimulated luminescence, or thermoluminescence (TL), is a property of many insulating materials, mainly in their crystalline form. It is a weak emission of light when they are heated, provided that they have been previously irradiated by ionizing radiation. Because the intensity of the emitted light is proportional to the amount of absorbed radiation (the “dose”), TL is mainly exploited as a dosimetric technique, that is, for measuring the absorbed dose.

In archaeology, TL is a means of dating ancient ceramic artifacts. In fact, crystalline inclusions are contained in the clay which originates from the ceramic material. These inclusions act as dosimeters for the natural radiation always present in any environment.

In extreme synthesis, the more intense the TL emitted by a ceramic, the higher its absorbed dose, and hence the longer is the time passed since the zeroing of the TL signal, when clay gave origin to the ceramic in the kiln. Practically, the more intense the TL, the older the ceramic.

The main dosimetric materials contained in ceramics are quartz (Martini 2014) and feldspars, but many other crystals may be present. TL is produced due to the presence of defects in the crystalline lattice. These defects can act as “traps” for the electrons released by the ionizing radiation. The following heating can “detrap” the electrons, which recombine in other defects, known as “luminescence centers,” which emit TL.

The possibility of dating pottery by TL was first proposed in 1960 at the Universities of Berne and California. Later, it was diffused as a dating technique in many countries and TL dating laboratories soon opened all over the world. Since 1978, the researchers involved have regularly gathered at the International Conference on Luminescence and electron spin resonance dating (LED), nowadays held every third year. TL soon had a dating

ally in optically stimulated luminescence (OSL), a related phenomenon exploiting light instead of heat to detrap the electrons. Because the zeroing event of OSL is the exposure to light, this technique is mainly exploited for dating the deposition of geologic sediments.

Both TL and OSL are absolute dating techniques, giving calendar results that do not need any external calibration. The ages obtained by TL range from a few tens to a few thousands of years, covering the whole period of the diffusion of ceramics.

The accuracy of a single TL date is typically around 10 percent of the age. When dating a number of coeval samples, the error associated with the average age can reduce to 4–6 percent. The basic equation for TL dating (and for every luminescence dating technique) is:

$$\text{Age (years)} = \frac{\text{Total absorbed dose}}{\text{Dose rate (Dose absorbed per year)}} \quad (1)$$

This formula gives the years since the last zeroing event (for TL, a heating to some hundred degrees Centigrade; Wagner 2004) experienced by the sample. For ceramics, this event generally corresponds to the firing in the kiln, which causes the release of any previously trapped electron.

Figure 1 shows a few TL curves (called “glow curves”) from ceramics of different age and origin. The glow curve represents the light emitted by a small aliquot of ceramic while heated from room temperature to about 500 °C. Such light is invisible to the naked eye and has to be detected by sensitive electronic devices like photomultipliers.

Looking at the scale of TL intensity (y-axes in Figure 1) it can be noted how different they are: The maximum intensity of the Etruscan bucchero is more than 40 times the intensity of the Renaissance bas-relief. This is only partly due to their different ages, and mainly due to the amount of crystalline inclusions: Evidently, they are much more present in the Etruscan object than the Renaissance one. To take these differences into account, artificial irradiation in a laboratory is necessary in order to assess the sensitivity to irradiation, as described in the following text.

DOI: 10.1002/9781119188230.saseas0580

Figure 1 Top curves: typical TL emission of different potteries. Clockwise from top left: Etruscan bucchero vase, sixth century BCE; Nok figurine, second century CE; Roman amphora, first century CE; Renaissance Florentine bas-relief, fifteenth century CE. Bottom curves indicate signal background.

The total absorbed dose (equation 1) is evaluated through TL measurements, after irradiation by calibrated radioactive sources on small samples already irradiated by the natural radioactivity. This is called the “additive dose” technique. The typical linear TL growth versus irradiation dose is shown in Figure 2 for a Roman amphora. The SI unit for the energy absorbed as a consequence of the interaction of ionizing radiation with matter, the absorbed dose, is the Gray, 1 Gy corresponding to 1 Joule/kg.

Responsible for the absorption of this energy, and consequently to produce TL, are the naturally occurring radioisotopes present in ceramic materials and in surrounding soils, mainly uranium and thorium radioactive families and ^{40}K (a smaller contribution is given by ^{87}Rb and cosmic rays). They emit α , β , and γ radiation which interact with matter and lose their energy, part of it being converted into trapped electrons. Typical

values of absorbed dose range from fractions of Gray to a few tens of Gray. The annual dose rate usually ranges from 1 to 10 mGy/year, because the radioactivity concentrations vary from one ceramic to another and from one soil to the next. α and β radiations, characterized by very short ranges, come from the internal radioactivity of the ceramic itself, while the environment contributes cosmic rays plus γ radiation which comes from a range of about 0.3 m around the sample.

TL dating requires small samples to be taken from the analyzed object. The necessary sample can be as small as a few tens of milligrams, when just a qualitative response is required as in an authenticity test. On the contrary, some grams of material are necessary to reach a higher dating precision.

Two main TL dating techniques have been developed: the fine-grain technique (Zimmermann 1971) and the inclusion technique (Fleming

Figure 2 Roman amphora (first century CE). (Left) TL curves induced by different irradiation doses (0–12 Gy) added to the natural dose. (Right) Corresponding linear TL growth.

1970). They prescribe two different recipes for preparing the ceramic samples in order to measure the TL signal and hence the total absorbed dose (equation 1).

In the first case, all the mineral grains originally present in the ceramic paste are taken, only selecting those grains that are small enough to allow full penetration by the short-range α particles (about 20–30 μm). The suitable grain size is 1–8 μm and for TL measurement it must be obtained in the form of a thin layer of a few microns thickness. This technique has the advantage of avoiding mineral selection, but the TL response to α irradiation, which is not the same as β and γ , has to be measured. Furthermore, possible adverse TL characteristics can occur, such as the anomalous fading of feldspars, an unpredictable escaping of electrons from deep traps at ambient temperature, and spurious TL.

The inclusion technique prescribes both granulometric and mineralogical separation. It uses only quartz grains of 80–120 μm dimension, that is, those that have experienced almost only β and γ irradiation. TL measurements are made on such quartz grains once their outer layer is etched away, so that the inner core are unaffected by the superficial interaction with α particles. TL is then only due to β , γ , and cosmic rays. The inclusion technique is based on quartz whose TL characteristics are well known and free from anomalous fading. The amount of material needed, often in the order of grams, depends on the concentration of quartz in the ceramics.

The dose rate (equation 1) assessment requires taking into account how the different components of radioactive decay interact with matter and transfer their energy to the ceramic (Aitken 1985). The adopted approach is the *infinite matrix assumption*: Within a volume greater than the penetration depth of the radiation, the rate of absorbed energy is equal to the rate of emitted energy. In other words, if the matrix is uniform (both in radioactivity and absorption coefficient), the dose—that is, the energy absorbed per unit mass—is equal to the energy emitted per unit mass, which can be calculated from the radioactivity concentration.

However, it must be noted that in almost every ceramic, some water is contained, or it has been contained over the centuries, which means that part of the emitted energy has been absorbed by water and not by the ceramic itself. In these cases, the effective annual dose is lower than the calculated one on the basis of the radioactive content of the ceramic and soil.

To practically evaluate the annual dose rate for equation (1), several techniques and methods have been developed. One possibility is to measure, with radiometric techniques, the radioactivity concentrations of the ceramic and soil, and then derive the corresponding contributions by means of purposely evaluated conversion factors, specific for the adopted dating method (Guérin, Mercier, and Adamiec 2011). Other calculations for additional experimental evaluations

like radon escape, disequilibrium, and leaching are also required.

Alternatively, dosimetric techniques allow us to directly obtain the various components of the dose rate with high precision and accuracy. Specifically, for gamma dosimetry, a capsule containing a few TL dosimeters is buried for a few months in place of the sherd to be dated to record the exact dose rate it experienced from outside.

Finally, the cosmic rays: In most cases their contribution is sufficiently small that a standard value of 0.15 mGy/year can be assumed for buried samples. Only in special cases (low sample radioactivity, high altitude) should adjustment of the standard value be considered.

The procedure for error-limit assessment is to calculate the percentage error in the date corresponding to a given error in each of the quantities or parameters on which the date is based. The random errors are due to luminescence measurements and to annual dose evaluations, while the systematic errors are mainly due to the calibration of laboratory radioactive sources. If TL age derives, as recommended, from the measurement of at least three coeval samples, the best value for the age of the context is the weighted mean of the individual ages. The overall error is the square root of the sum of the squares of the individual errors, and a standard error on the average age is also quoted.

As already mentioned, TL is typically applied to ceramic material, which means not only pottery but also bricks; therefore, the dating of buildings can be afforded. TL can also be used to date the clay core of bronze statues, as mentioned in the following case study.

Like any other dating technique, TL can be used if the conditions of its applicability are satisfied, keeping in mind its intrinsic characteristics. TL dates the last heating of the material, which means that in some cases the calculated age might not be related to the archaeological event under study, owing to the possibility of reuse (TL age older than expected), or restoration or fire (TL age younger than expected). When applied to archaeology, a detailed stratigraphic analysis is very useful before sampling, in order to identify samples whose age can be correlated to that of the archaeological layer.

To be successful, a dating campaign must be carefully set up (stratigraphic analysis, selection of the key sampling points, availability of materials and soils). No precise dating can be performed on samples whose archaeological context was lost or questionable, nor should analyses be done on a single sample, but at least on three coeval samples. The contemporary use of other techniques like radiocarbon, OSL, or dendrochronology is recommended, if affordable. The precision of the results can be further enhanced by an appropriate use of the Bayesian statistic (see BAYESIAN STATISTICS) that combines in a single formal analysis the experimental results with historic information about samples and provenance sites.

Case studies

In many cases, TL dating allows establishing, deepening, or refining the chronology of an excavation site and, through it, of a past society. The time span of the rise and fall of the Peruvian Moche culture at the Sipán site and assessment of the continuity of the Mỹ Sơn Hindu religious settlement from the fourth century to a couple of centuries beyond the Vietnamese military conquest in the fifteenth century are just two examples of the integrated approach mentioned above (Maspero, Sibilia, and Martini 2016).

Sipán is a Moche site located in the desert coastal zone of northern Peru, consisting of two mud-brick pyramids higher than 35 m, and a smaller connecting platform. Since its fortuitous discovery in 1987, it has soon appeared as one of the richest and most extraordinary funeral complexes of the region: Sixteen tombs have been excavated, revealing precious and enormous information regarding the Moche culture, which developed in that region from 100 to 700 CE. TL dating was performed, together with radiocarbon accelerator mass spectrometry (AMS) dating, on a number of samples from the key structures of the settlement, to establish a reliable, scientific-based chronology, particularly controversial for the final phase. Our dating results documented the occupation of the site since the beginning of the third century until its abandonment during the sixth century period. Moreover, the production and use of ceramics stylistically

referred to the more ancient phases (Moche II and III) continued without interruption until the abandonment of the site (Aimi et al. 2016; Maspero et al. 2016).

Although TL has become well established in the field of archaeology, it has very good potential also in the history of buildings with the possibility of identifying alterations, repairs, and restoration phases that may have occurred since the original construction (Guibert et al. 2009).

Mỹ So'n, the Vietnamese sacred site of the kingdom of Champa (fourth–fifteenth century CE), inscribed since 1999 in the UNESCO World Heritage List, consists of the remains of a series of impressive Hindu tower temples, which have survived centuries of abandonment, severe war damages, and controversial restorations. Mỹ So'n is an archaeological site of primary importance for the knowledge of Vietnamese history and culture. A Vietnamese–Italian joint research project allowed archaeological excavation on site, focusing on the G temple group. Prior to the consolidation and restoration works, more than 50 samples were taken from almost all the structures of one of the temples and dated by TL. The results allowed archaeologists to identify and place in chronological sequence the edification of the different buildings, which occurred at various times during the twelfth century. Moreover, older potteries were found, reused from other abandoned buildings in the same area (Martini et al. 2008; Maspero et al. 2016).

A further dating application is to clay cores, the ceramics-like residual of the fusion activity of bronzes, fired during the fusion itself. In many cases, their analysis can be crucial to determine the age of renowned masterpieces, whose chronological assignment is sometimes controversial. This is the case with the Lupa Capitolina, a symbol of Rome, traditionally considered to be of Etruscan age. TL dating, together with results of the analysis of alloys and production techniques, definitely excluded Etruscan production, confirming its fusion in the medieval age (Martini and Sibilia 2009).

When TL dating cannot be performed properly—for instance, in the case of single samples out of context—a simplified TL test to check their authenticity can be done. A very small amount of ceramic is needed, some tens of milligrams, to measure the total amount of TL of

the sample in order to verify its compatibility with the expected value, inferred from the presumed age, without measuring its radioactive content, which needs much more sample. In other words, the TL test only tells us if a vase is *antique* or *young*, allowing us to distinguish between an original piece and a modern copy.

Transmission Electron Microscopy

STEFANO GIALANELLA

University of Trento, Italy

Transmission electron microscopy (TEM), together with the companion technique, scanning electron microscopy (SEM), is regarded as one of the most powerful characterization tools for materials (Newbury and Williams 2000). This is also reflected in the abundant literature, textbooks, and specialized journals concerning these two microscopy techniques. A variety of specific instrumentation has been developed over the years to comply with the requirements of different classes of materials (see SCANNING ELECTRON MICROSCOPY). TEM and SEM, in association with relevant spectroscopy tools, such as energy dispersive X-ray spectroscopy, are gaining increasing importance in the study of materials for conservation (see ELECTRON MICROSCOPY IN CONSERVATION) and archaeology (see TEM AND ARCHAEOLOGICAL MATERIALS).

The development of the instrumentation for modern TEM began in the 1930s with the pioneering experiments by M. Knoll and E. Ruska. Ruska was awarded the Nobel Prize in Physics (in 1986) for his major contributions to the fundamental principles of electron microscopy (Ruska 1987). The initial idea for the development of electron microscopy was to overcome the submicrometric resolution limits of optical microscopy (see OPTICAL MICROSCOPY), essentially determined by the wavelength of visible light (200–700 nm), by using high-energy electrons. The De Broglie wavelength of electrons accelerated by voltages of 100–400 kV lies in the range of 0.00370–0.00164 nm. The ultimate resolution in state-of-the-art electron microscopes is limited by the aberrations affecting the magnetic lenses, particularly the objective lens, present in the optoelectronic column of the microscope. Sub-angstrom resolution has been achieved by compensating for these aberrations, particularly

the spherical and chromatic aberrations, using suitable correction systems and energy filters, with the possibility of imaging atomic arrangements and relevant defects with high-resolution TEM (HRTEM) images (Haider et al. 2009). HRTEM requires significant software support for modeling images obtained using *phase contrast* principles, based on the interference among the many beams crossing the observed sample region. The specific requirements for an observable HRTEM specimen are definitely more restrictive, particularly with regard to its limiting thickness and homogeneity, as compared with conventional TEM specimens. However, atomic resolution images are not usually required in archaeological science, and in this field, conventional TEM is a more important experimental tool for achieving a complete microstructural, crystallographic, and chemical characterization of the analyzed materials. This can be achieved thanks to the flexible imaging modes, electron diffraction methodologies and high spatial resolution spectroscopies.

Contrast in TEM images is determined by *mass thickness*, *diffraction* or, indeed quite commonly, a combination of the two. Mass thickness contrast is determined by the differential absorption of electrons by regions of the specimen having different average atomic number and therefore electron absorption coefficients.

Diffraction (see DIFFRACTION) *contrast* is determined by the scattering phenomena of the electrons by the crystalline lattice and structural defects present in the sample. Bright field (BF) and dark field (DF) images are obtained using the transmitted and diffracted beams respectively. These images convey information on the structural features of the investigated specimen, as shown by the images in Figure 1. The BF (Figure 1a) and DF (Figure 1b) images from the same field of view of a synthetic fluorite (Ca₂F) specimen are shown, demonstrating the reason for the two complementary imaging modes. BF images are produced by the transmitted (not deflected) beam. The transmitted beam is the brightest spot at the center of the selected area electron diffraction (SAED) pattern (Figure 1c),

surrounded by the diffracted beams. From the DF image, the average crystallite size can be better appreciated, looking at the brighter speckles originating from individual scattering domains.

Other important imaging modes can be implemented in a TEM through the scanning transmission electron microscopy (STEM) mode, in which, like in conventional scanning electron microscopes, a focused beam is scanned point-by-point across the sample surface. The transmitted signals are collected by specific detectors and form BF and DF images accordingly. An additional imaging option is available for DF images, associated with high-angle scattered electrons, forming the so-called high-angle annular (detector) dark field (HAADF) images. Since electron elastic scattering depends on the atomic number, these images are usually referred to as

Z-contrast images. It is worth saying that the highly coherent electron beam used in STEM mode, and the incoherence introduced in the transmitted beam by the high-angle scattering, is somewhat analogous to the *phase contrast* used in HRTEM. In fact, in STEM subnanometric resolutions can also be achieved, and for this reason this technique should also be regarded as a high-resolution imaging tool (Erni et al. 2009).

Electron diffraction, already mentioned with reference to *diffraction contrast*, also provides essential data for crystallographic investigations, for which SAED is probably the most commonly used methodology. A physical aperture is inserted in the first image plane of the microscope to select the region of the sample from which the relevant diffraction pattern is produced, thanks to the diffraction principles operating in elastic

scattering phenomena and employed in other diffraction-based crystallographic techniques, like X-ray diffraction (XRD) and electron backscatter diffraction (EBSD, see ELECTRON BACKSCATTER DIFFRACTION (EBSD)). From these data, the identification of the crystallographic phases present in the specimen can be attained, along with their orientation with respect to each other and to the incident electron beam. The minimum size of the area that can realistically be selected depends not only on the diameter of the selecting aperture, but also on the aberrations associated with the scattering by the edge of the aperture itself, which are increasingly important for lower aperture diameters. Considering that a magnification of $\times 50$, or close to this value, is obtained in the first image plane of conventional TEM, with apertures having minimum diameters of 5–50 μm , a real area not smaller than 0.1–1.0 μm diameter can be selected. Depending on the microstructure of the sample, spot or ring patterns can be attained, as displayed in Figures 2a and 2b, respectively. The first is obtained from one of the aluminum crystalline grains (i.e., single crystal regions) displayed in the TEM micrograph in Figure 2c. The second SAED pattern refers to the nanostructured polycrystalline carbon fibers in Figure 2d.

Diffraction patterns from significantly smaller regions can be acquired, by focusing the incident electron beam on the sample surface using the condenser lens system of the microscope. This operating mode is usually referred to as convergent beam electron diffraction (CBED), useful for crystallographic characterization down to the nanometer scale. Moreover, the fine analysis of the CBED patterns may provide additional information on the sample, like the presence of lattice strain, an accurate estimation of the lattice parameter, and evaluation of the thin foil thickness in the sampled regions (Tanaka and Tsuda 2011). The high coherence of the incident electron primary beam in STEM mode, particularly in field emission gun (FEG) instruments, has disclosed the possibility of recording diffraction patterns from extremely small volumes, with diameters of 1 nm or less (Cowley 2004).

The inelastic interactions of the incident beam with the TEM sample result in the emission of secondary radiations, like X-rays and Auger electrons, and in changes in the energy of the primary

electrons. Since these effects and the intensity of the resulting signals also depend, through specific cross-sections and related parameters, on the concentration of the interacting atomic species, relevant spectroscopies have been developed. The emission of Auger electrons from a TEM thin sample is too weak to be realistically interesting for practical purposes. Energy-dispersive X-ray spectroscopy (EDXS) and electron energy-loss spectroscopy (EELS) are the two techniques more frequently available in TEM instruments. EDXS is based on the electron-induced emission of high-energy X-rays produced by the ionization of the inner electron shells. Since the energies of the emitted X-rays represent a sort of fingerprint of each specific element, the qualitative composition of the analyzed material is the first information that can be easily obtained from this technique. Using correction programs and suitable calibration procedures, often simplified by the availability of virtual standards archives, a quantification of the chemical data is quite straightforward, considering that the so-called “matrix effect”, comparatively more important in the case of SEM bulk samples, can be overlooked in many TEM specimens. In terms of analytical aspects, EELS is particularly recommended for low atomic number elements ($Z < 11$), being in this respect an excellent technique to be integrated with EDXS, which is better suited for higher atomic numbers. For both techniques, a central role is played by the detection systems, which are particularly sophisticated and therefore costly for EELS. EELS detection systems are spectrometers capable of discriminating electrons with different energies, after having interacted with the TEM sample, using magnetic deflection prisms. In this way, it is also possible to select electrons over a narrow range of energies for high-resolution imaging, removing chromatic aberration, and chemical mapping. The electron energy has to be selected close to the absorption edge of the elements to be mapped. Chemical X-ray maps can also be acquired using EDXS coupled to STEM instruments, according to principles and procedures similar to those used in SEM.

The availability of a suitable TEM sample is a prerequisite for any of the above analyses and observations. The most obvious requirement for a TEM specimen is that the region to analyze is electron-transparent. From a practical

Figure 2 (a) Spot SAED pattern from one of the Al grains displayed in (c). Face-centered cubic crystalline structure. (b) Ring SAED pattern from the carbon fibers in (d). point of view this means that inorganic (metallic alloys, ceramics, glasses, etc.) TEM specimens should have thicknesses in the 10–100 nm range. A greater sample thickness, up to 1 μm or so, is admissible for organic, low atomic number materials, like polymers and biological materials, featuring lower absorption coefficients for electrons. Some samples, like thin films and powders, may already satisfy these transparency

requirements, and therefore they can directly be observed without any thinning procedure. Otherwise, an appropriate sample preparation procedure should be selected, capable of reaching the right electron transparency without altering the genuine, pristine material features. In the case of bulk samples, the first step is a preliminary thinning, based on mechanical cutting, grinding and polishing, to take the specimen thickness

down to 0.1–0.5 mm. For the final thinning, different techniques are available, to be selected on the basis of specific material properties. Metallic materials can be chemically thinned, possibly using electrochemical cells that render the process more controllable and reproducible. Multiphase alloys, ceramics and, in general, ceramic and metal matrix composites can be better thinned using ion-milling, selecting the milling conditions so to avoid, or at least reduce, the effects of ion implantation, radiation damage, or material redeposition. The ultimate evolution of ion-based tools is the focused ion beam (FIB) equipment that can produce ion thinning in a much more controllable way, particularly when coupled with an SEM column (dual beam system) to monitor the thinning in real time and to manipulate the thin foil in the vacuum chamber. This is usually transferred onto a carbon-coated TEM grid, or welded to it for safe transportation, and inserted into the TEM column. This controlled ion-slicing, featuring the additional remarkable advantage of pin-point selection of the interesting part of the sample, may have important advantages for archaeological applications of TEM. Direct cutting of ready-to-observe slices of, mostly, organic and biological samples can be prepared via cryogenic ultra-microtomy. Using mechanical cutting with extremely sharp diamond or glass knives and a very precise positioning system, allowing nanometer-scale displacements, an ultra-microtome can cut thin foils directly from the original bulk sample. Since the slices are extremely delicate, after being cut they are floated onto the surface of alcohol or similar low-temperature freezing liquids, and collected using a standard TEM grid for easy positioning in the TEM sample-holder.

An important practical aspect to consider is the total volume available inside the microscope for each sample. For standard TEM instruments, the whole specimen should fit inside a cylindrical volume, 3 mm in diameter and 0.2–0.3 mm in height. In general, the observable regions will be centered with respect to these dimensions, and this is an additional task that the final thinning technique should be able to accomplish. Of course, it is also important that the interesting features of the archaeological find fit inside the above volume. In general this is not a serious limitation, and actually the high resolution and high sensitivity of

TEM can be exploited to limit to a minimum the size of the sample to be analyzed, which may just consist of fragments mechanically scraped out from the regions of interest, and already feature electron-transparent regions. However, TEM observations, being restricted to comparatively small volumes of a material specimen, require a larger-scale validation of their actual representativeness. In the case of samples with coarse microstructural features, TEM specimens from different pinpointed regions should be sampled accordingly. Moreover, as reported in studies using TEM for the characterization of archaeological finds (see TEM AND ARCHAEOLOGICAL MATERIALS), electron microscopy observations are usually carried out in association with bulk analyses, using optical microscopy (see OPTICAL MICROSCOPY), scanning electron microscopy, X-ray diffraction (see XRD AND MATERIALS ANALYSIS), or X-ray fluorescence (see X-RAY FLUORESCENCE SPECTROMETRY (XRF)) and X-Ray Fluorescence Spectrometry (XRF), which provide an important general framework to the TEM results.

Vibrational Spectroscopies

JUAN M. MADARIAGA

University of the Basque Country (UPV/EHU), Spain

Archaeological objects are mixtures of different chemical compounds. Each chemical compound is unique (it has a given chemical formula that is different from the other compounds) and hence it has unique molecular vibrations (movements among the different elements of the chemical formula). Each vibration has a spectroscopic response in the form of a band at a given wavelength. Such molecular vibrations (the collection of all the spectroscopic bands) are like the fingerprint of each chemical compound. The vibrational spectroscopies are analytical instrumental techniques that measure such molecular vibrations, giving us the spectrum with the different spectroscopic bands (like the fingerprint) of each chemical compound.

Vibrational spectroscopies are techniques to obtain easily the information about the compounds present in any archaeological material, whatever the nature of such compounds: original from the body of the object, newly formed as a consequence of the interaction between the object and the surrounding environment (air, water, or soil), or degraded from the original compound. These techniques can measure powdered materials (around 200 mg) and till spot areas of 1–500 μm on the surface of objects, allowing the possibility to perform macro and micro till analysis.

There are two major vibrational spectroscopies: one based on infrared (IR) radiation as the excitation source, and the other measuring the Raman effect promoted by the excitation of molecules with lasers of different wavelengths. The basis of vibrational spectroscopy techniques, the possibilities for qualitative, quantitative, and classification analyses, and the available databases and search libraries (algorithms) are well described in a recent book (Chalmers, Edwards, and Hargreaves

2012). Currently, IR instrumentation is based on the so-called Fourier transform interferometer (FTIR), while the Raman technique has instruments using Fourier transform interferometers (FT-Raman) but most of them measure the Raman scattering through dispersive Raman spectrometers (Raman as such).

The spectral range of both vibrational spectroscopies is similar. IR spectroscopy covers three spectral ranges: (1) near infrared (NIR) in the 280–2,500 nm range of wavelengths (14,000–4,000 cm^{-1} in wave numbers); (2) middle infrared (mid-IR or simply IR) in the 2,500–25,000 nm (–25 μm) range of wavelengths (4,000–400 cm^{-1} in wave numbers); and (3) far infrared (FIR) in the 25–1,000 μm range of wavelengths (400–10 cm^{-1} in wave numbers). Raman spectroscopy usually covers the 2.5–100 μm range (4,000–100 cm^{-1} in wave numbers). Both spectroscopies have instruments to measure archaeological objects in the laboratory (point-by-point at macro and micro level, or with spectroscopic imaging of surfaces) or use fiber-optic-based probes to measure directly in the field (portable, handheld, remote, and stand-off devices) without the need to take samples from the objects (Chalmers et al. 2012).

IR and Raman spectroscopies are mainly used to identify chemical compounds based on the different spectroscopic responses of the molecular groups belonging to the compound. This identification can be done for organic and inorganic compounds, in crystallized or amorphous forms, and in solid, liquid, or gaseous states. These possibilities of the vibrational spectroscopies offer better performances than other classical analytical techniques applied in archaeology. IR and Raman spectroscopies are not alternative analytical techniques but complementary because some vibrations are not active in IR, others are not Raman sensitive, and others have both possibilities of detection. For example, most metal-oxygen vibrations in oxide compounds are inactive or difficult to detect by IR spectroscopy, while Raman spectroscopy is well suited for such kinds of chemical compounds appearing

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0594

often in archaeological objects. On the contrary, all of the organic compounds (formed by complex molecules with different molecular groups) have both IR and Raman responses, but the IR bands are more selective and sensitive than the Raman ones.

The number of research works and reviews dealing with the use of vibrational spectroscopies to study archaeological objects is increasing continuously. When you type “infrared spectroscopy in archaeology” in the Chemical Abstract database, 413 direct references are displayed and another 1,815 related ones appear. When typing “Raman spectroscopy in archaeology,” the direct number of references increases to 706 while the related references extend to 1,571 research works (data correct as of the end of August 2016). At the beginning, scientific analyses were focused on the characterization of the nature and composition of original materials (stones, organic remains, porous materials, etc.), IR spectroscopy being the analytical technique of choice for standard laboratories working in the field of archaeology; a review (Bacci 2000) included 110 references for works published in the twentieth century on different topics in art and archaeology, and regarding the use of three IR modes: ultraviolet–visible–near infrared (UV-VIS-NIR), FT-IR, and fiber optics reflectance spectroscopy (FORS). When new laser sources became available, Raman spectroscopy started to be the leading spectroscopic technique used in the 1990s (Chalmers et al. 2012), as also observed from the works referred to in the last review published on the use of Raman spectroscopy to identify minerals as the key issue to solve problems in archaeology (Bersani and Lottici 2016).

Analytical techniques and methodological approaches developed in the field of materials science are now widely applied to archaeological objects to gain information about the material composition and structure, to understand the method of manufacturing artifacts, to ascertain the burial influence on the conservation state of the objects, and to identify the stressors that are acting as degradation sources on the objects. In a recent review, Sciau and Goudeau (2015) proposed the study of heterogeneous and complex materials of ancient pottery using an innovative approach by identifying subsystems of materials and applying traditional and novel analytical

methods to scan the whole material at different scales.

One such novel analytical setup is synchrotron-based Fourier transform infrared microspectroscopy (SR-FTIR), a high-level instrumental technique increasingly employed in archaeology. The technique combines the advantages of FTIR spectroscopy with the extra potential of chemical imaging and the properties of the synchrotron source of radiation. The first applications were reviewed some years ago (Cotte et al. 2009), including the fundamental aspects of the IR synchrotron source. More recently, another review has shown the capabilities, advantages, and disadvantages of current and future SR-FTIR spectroscopy, alone or combined with other SR techniques (radiography/microscopy, X-ray diffraction, X-ray fluorescence (XRF), X-ray spectroscopy) to characterize the original materials and degradation compounds in the field of archaeometallurgy (Young 2012).

FTIR imaging started to be used some years ago, with and without the aid of SR sources. Since 2010, several research works have described the fundamental aspects, accessories, and applications in both micro- and macro-attenuated total reflectance (ATR) imaging, covering the applications of both imaging techniques to, among others, archaeological and other heritage objects. Some recent works also used not only the mid-IR spectral region but also the NIR one to increase the capabilities of the different modes of IR spectroscopy.

The possibilities of IR have been extended with the introduction of commercially available portable/handheld instruments, working in three modes. One uses the contact capabilities of FORS to measure the reflectance of illuminated samples in the mid-IR region, focusing IR radiation vertically through an optical fiber and collecting the reflectance also vertically through a second fiber; the disadvantage of this configuration is the interference produced by the specular reflection in some samples. The second is known as diffuse reflectance infrared Fourier transform spectroscopy (DRIFTS), working in the mid-IR range, also a contact portable device where the two optical fibers are positioned at different incident angles in the head of the instrument, allowing reduction of the effect of the specular reflection to only one principal IR band; with this

system (and also with FORS) the identification of compounds must be done using the secondary and combination IR bands, an effective practice although not used when working with other FTIR systems (transmission/absorption or ATR) where the identification is based on the main IR bands. The third mode measures NIR reflectance in a stand-off mode (at distances greater than 1 m), promoted by illumination of the sun on the archaeological objects.

The first work using Raman spectroscopy in this field was published in 1984 using a Raman laser microprobe to analyze the pigments of painted manuscripts and archaeological materials. Since then, Raman microscopy and Raman microprobe modes have been extensively used throughout the last century to characterize materials (archaeological and historic ceramics, Roman intaglios, pre-Spanish ceremonial gemstones, pigments of pre-historic rock art paintings, Roman mural paintings, etc.) but also to ascertain past technology for manufacturing archaeological Egyptian blue and green pigments. With the advent of the new century, the number of research groups using Raman spectroscopy increased, and consequently new findings were published, covering not only the characterization of original compounds in archaeological objects but also the nature of degradation products (efflorescence crystals, biofilms, unexpected compounds on the surfaces of excavated materials, etc.), that were not previously described, the influence of environmental conditions on the conservation state of the objects, and some new strategies in the conservation of the objects.

Most of these new findings have been presented in the biannual edition of the International Congress on the Application of Raman Spectroscopy to Art and Archaeology (RAA series), which started in 2001. The eight editions of this dedicated congress is a measure of the current importance of Raman spectroscopy in archaeological research. Some of the contributions are selected to be published as peer-reviewed papers; these contributions can be found by searching the references collected in the editorial of the last edition (Ropret and Madariaga 2014).

From the first edition, the importance of the development of a mobile Raman system was clearly seen. The historical developments of such spectrometers to perform field analysis

are detailed in references 4–14 of the review by Bersani and Lottici (2016). Nowadays, most of the instrumental companies in the field of Raman spectroscopy offer mobile systems, from portable to handheld devices, working with one (1,064, 785, and 532 nm) or two lasers as excitation sources, and with different resolutions and sensitivities. Now we have commercially available portable spectrometers with better performance than the standard laboratory instruments of the past century. These facilities give us the possibility to go directly to the settlements and perform high-level research directly in the field.

One important property of some chemical compounds is the change to different chemical forms (different molecules in practice) with temperature. For example, in the family of gypsum ($\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$) this compound is stable from ambient temperature to 45 °C. If the object containing gypsum is heated up to this temperature, the compound dehydrates to bassanite ($\text{CaSO}_4 \cdot \frac{1}{2}\text{H}_2\text{O}$), which is stable in the range 45–110 °C. If the heating process continues, the next compound is anhydrite type III ($\gamma\text{-CaSO}_4$, hexagonal), a soluble phase stable between 110 and 300 °C; then it becomes anhydrite type II ($\beta\text{-CaSO}_4$, orthorhombic), an insoluble and stable phase in the range 300–1,180 °C; and finally the end member of this family is anhydrite type I ($\alpha\text{-CaSO}_4$, cubic), the most insoluble and stable phase at temperatures higher than 1,180 °C. These compounds have different Raman spectra, giving us the option to have an indirect thermometer analyzing the spectrum of the sample. Thus, if we detect only the presence of anhydrite type II, this means that the sample has never reached the temperature of 1,180 °C. In some cases, mixtures of two spectra of the same family are found; using a mathematical tool, the spectrum is decomposed using the sum of XX percent of compound-1 plus YY percent of compound-2 (with $\text{XX} + \text{YY} = 100\%$) and this is used to provide a better estimation of the temperature; thus, if we have 70 percent bassanite and 30 percent anhydrite type III, this means the object has reached around 120–130 °C.

The thermal properties and associated Raman spectrum of different mineral phases that can be used as indirect thermometers are detailed in the review by Bersani and Lottici (2016), including examples applied to ceramic, lapidary

objects, archaeological gemstones, and mineral pigments. In the particular field of archaeological and historic ceramics, the change of the Raman spectrum as a function of temperature has been largely exploited to ascertain the firing conditions of manufacture, as well as those of the glazed decorations on such objects; some examples and references of the possibilities offered by Raman spectroscopy in this field are also included in the review by Sciau and Goudeau (2015) and the book by Chalmers et al. (2012).

Changes in the original compounds start at the moment of burial of the object. This burial is usually done by sediments (soil particles in very wet conditions), and, with time, the amount of such sediments increases and, in practice, soils appear on the top. Such soils can be natural (plants and grass covering the outermost layer) or cultivated (farming with natural or chemically amendment products). These soils are continuously washed by the rain that incorporates ions taken from the atmosphere, especially CO_2 , an acid compound when dissolved in water (carbonic acid, H_2CO_3) with a high chemical reactivity. If the archaeological settlement is in an area with a polluted atmosphere, other chemicals like sulfates, nitrates, and light carboxylic acids will be dissolved in the rainwater; if the settlement is near a coastal area, the marine aerosol (chloride, sulfate, sodium, magnesium, etc.) is always incorporated in the rainwater. When these waters percolate (vertical displacement of the waters through the soil layers) the initial dissolved ions are enriched by dissolution of the compounds present in the top of the soil; in this case, special attention must be paid to ammonium nitrate (NH_4NO_3)—a salt always present that has an acid in the cationic side (NH_4^+) and in the anionic side a harmful compound (NO_3^-) from the conservation state point of view.

Depending on the nature of the atmosphere and the soils of a particular settlement, the dissolved ions and compounds in the rainwater reaching the archaeological objects can be very significant. These ions can start interacting (by chemical reactions) with the compounds originally present on the surface or in the bulk of the objects, leading to a very complex set of new chemical compounds that compromise the conservation state of archaeological objects when excavated. Fortunately, Raman spectroscopy is

sensitive enough to detect such new chemical compounds (the decaying products), being the analytical technique of choice to diagnose the conservation state of excavated objects.

A multidisciplinary work performed by archaeologists, museum restorers, and chemists (Veneranda et al. 2016) is a good example of the current possibilities of research. The aim was (1) to characterize the conservation state of copper-based alloys (several buckles) and iron-based (one spur) medieval objects found in an excavation at only 20–40 cm depth, in a settlement at 400 m above sea level but with the direct influence of marine aerosol, and (2) to ascertain which chemical reactions took place on the objects to explain the formation of the corrosion compounds. First, the soils were characterized, especially the soluble ions present. Second, the corrosion compounds (vibrational spectroscopy techniques are not sensitive to metallic elements like copper and iron) were identified in both kinds of objects using two portable Raman spectrometers (using 785-nm and 532-nm excitation lasers). A key corrosion compound, akaganeite (an iron hydroxide with chloride inside), was detected that conditioned the election of the conservation procedures in the museum in order to minimize the influence of chlorides (this particular compound cannot be detected by IR spectroscopy). Finally, the authors were able to ascertain the chemical reactions promoting the formation of all the detected corrosion compounds, identifying the impact sources affecting the archaeological objects. In this work, other analytical techniques were used, complementing the information obtained by Raman spectroscopy.

The use of other analytical techniques to complement the vibrational spectroscopic information is a clear trend in the future (see Further Reading). As an example of this trend, another multidisciplinary work can be cited (Hernanz et al. 2014 and supplementary information) where archaeologists, chemists, geologists, conservators, environmental managers, and heritage managers worked on five rock-shelters with significant examples of the Levantine and schematic rock-art of the Iberian Peninsula. First, field analyses were performed with portable Raman and DRIFT spectrometers, selecting microsamples of interest to perform further analyses in the laboratory

using Raman microscopy and Raman imaging, all vibrational spectroscopic techniques. The work describes well the measurement constraints when using micro-Raman spectroscopy in the field and how these can be overcome. The results were complemented with portable (XRF) and laboratory (scanning electron microscopy coupled with energy dispersive spectroscopy (SEM-EDS)) instruments for elemental analyses, obtaining the same picture for the different pictographs: the painted layer is over a series of geological layers and above another set of layers naturally formed hundreds of years after the painting process.

X-Ray Absorption Spectroscopy (XAS, EXAFS, XANES)

SIMONA QUARTIERI

Università di Messina, Italy

Introduction

Synchrotron photon-based methods (see SYNCHROTRON-BASED X-RAY ANALYTICAL TECHNIQUES AND MATERIALS ANALYSIS) are increasingly being used for the physico-chemical and structural study of ancient and historical materials (e.g., in archaeology, conservation sciences, paleontology, etc.). Parameters such as the high photon flux, the small source size, and the low divergence attained at the synchrotron make it a very efficient source for a range of advanced spectroscopy and imaging techniques, adapted to the heterogeneity and great complexity of the materials under study. Among the synchrotron-based X-ray methods, X-ray absorption fine structure spectroscopy (XAFS) has been relatively recently applied to heritage studies, and it is now widely used since it offers a combination of features particularly well-suited for the study of rare, ancient materials and works of art (Quartieri and Arletti 2013; Farges and Cotte 2016). XAFS techniques—including pre-edge, X-ray absorption near-edge structure (XANES) and extended X-ray absorption fine structure (EXAFS) regions—are non-invasive, have low detection limits, afford high lateral resolution, and provide exceptional chemical sensitivity. They can be applied in air and have virtually no restrictions on the type and size of the sample, they are applicable to most of the elements of interest, even at very low concentrations, and, finally, to a wide variety of materials, ranging from hard matter such as glass, ceramics, and metals, to softer materials such as paintings, bone, wood, and paper. All these characteristics are highly

desirable for the scientific investigation of precious, heterogeneous, and complex materials. In particular, the chemical mapping capability, with high spatial resolution that provides information about local composition and chemical states, even for trace elements, is a unique asset.

The XAFS studies of cultural heritage in general aim to understand (1) the geographical provenance and original fabrication processes, and/or (2) the degradation reactions undergone by the ancient materials. The former mostly concerns the craftsman's control over synthetic reactions at high temperature, resulting in various optical effects in glasses, glazes, lusters, ceramics, and pigments. The latter—more concerning paintings, bone, wood, and paper—occur over longer timescales and are either due to past conservation treatments or due to passive external circumstances, or may even be an inherent part of the chemical composition of the artwork itself.

Basic principles of XAFS and experimental approaches

X-ray absorption spectroscopy (XAS) techniques are based on the measurement of the variation in the absorption coefficient while scanning the incident X-ray photon energy in a narrow region around an absorption edge (Figure 1). This variation is physically related to the excitation cross-section of the core electrons into unoccupied electronic states or into the vacuum continuum. The spectral features observed close to the absorption edge, referred to as X-ray absorption near-edge structure (XANES) (Figure 1), depend on the local molecular environment (oxidation state, coordination numbers, site symmetry) of a given absorbing atom, and also provide the basic mechanism for imaging with chemical specificity. The extended X-ray absorption fine structure (EXAFS) signal is measured when the energy of the incoming X-rays is scanned far beyond the absorption edge of interest. Constructive and destructive interference between the outgoing and backscattered photoelectron waves results

in EXAFS oscillations. The analysis of these signals provides information on the identity of the surrounding atoms, specific bond distances, and coordination numbers.

Due to the high absorbance of most materials encountered at energies below 20 keV, most X-ray absorption experiments in the fields of archaeology and Cultural Heritage (CH) are performed using XANES in fluorescence detection mode, by collecting the signal typically over some tens of electron-volts. The XANES fingerprint obtained is interpreted by comparison with a number of reference compounds.

Interestingly, during these experiments, spot spectra can be collected with typical beam diameters from a few hundreds down to a few microns—referred as μ XANES and μ EXAFS measurements—and combined with other X-ray microbeam-based techniques, such as μ -fluorescence analysis or imaging. These multi-technique approaches have proven their value over more conventional combinations of methods, especially for the study of highly heterogeneous or decorated samples, and for the characterization of degradation products that are formed in thin layers at the surface of weathered archaeological and/or artistic materials and artifacts. Actually, since both degradation and fabrication processes (selected raw compounds, production reactions, temperature, atmospheric conditions, etc.) are usually based on oxidation–reduction reactions, XANES analysis is a powerful tool to understand the life and evolution of art materials.

Elements and materials

Although XAFS techniques can be applied to almost all of the chemical elements of the Periodic Table, not all are equally studied. Fe and Cu clearly attract major attention. The main reason is their almost ubiquitous presence in artistic materials and coloring properties, being in pigments (see CHARACTERIZATION OF PIGMENTS), inks (see INK), but also glass or metallic artifacts (see CHARACTERIZATION OF METALS AND ALLOYS). Similarly, Mn is present in various natural mineral or biogenic pigments, as well as in glasses.

These elements, being transition metals, are chromophores, and their electronic state is usually responsible for the optical appearance of artworks. In addition to other heavy metals such as Cr, Ag, Sn, and Sb, they are increasingly analyzed by XAFS techniques to gain new insights into the chemical origin of color and of optical effects, in particular in glasses and ceramics, such as opacity, iridescence, metallic luster, and shine. As aforementioned, XAFS techniques are extremely suited for the analysis of such materials because, being based on short-distance probes, they can be equally applied to crystalline and amorphous samples. When performed in fluorescence mode, the selective analysis of minor diluted elements is possible, even in complex mixtures. Indeed, the above-mentioned optical effects are frequently obtained by introducing small quantities of these chromophores.

On the other hand, an increasing number of works aim at understanding the evolution of

these materials with time (degradation, corrosion, paper aging—see PAPER ANALYSIS). For instance, problems caused by alteration in paintings, metals, or wood (see DETERIORATION OF WOOD) have been investigated by many experiments conducted at the S and Cl K-edges. These elements can have an exogenous origin, and XAFS enables us to determine their influence on the artistic materials (Bertrand et al. 2012).

Selected examples of XAFS heritage studies

The goal of the entry is to illustrate, not exhaustively, some of the main applications of XAFS to heritage objects. Most of the examples here selected, and many others of great interest to archaeologists, curators, conservators, and art historians, are reported and discussed in the reviews cited in the introductory section.

Archaeological and stained glass

XANES and EXAFS techniques were first applied to *ancient glass*, and thanks to the peculiar characteristics of these methods, they are presently widely used to study non-crystalline ancient materials. Recent reviews of this topic and of the correspondingly rich literature are provided by Quartieri and Arletti (2013), and Farges and Cotte (2014). Interested readers are invited to consult the bibliographic references cited therein.

The first pioneering work was by Nakai et al. (1997), who performed a XANES study on glass samples and ceramic sherds excavated from a site in Turkey, providing information on the chemical nature and on the oxidation state of the colorant elements. Actually, most XAFS applications to historical glass research have been devoted to interpreting the origin of the artifact's color. Scientific analysis on this topic may provide important information on the ancient production technology and on the selection of ingredients responsible for color and opaque effects.

The color exhibited by glass (see GLASS COLOR) can depend on the oxidation state and the electronic configuration of the constituent metal ions. These are usually elements belonging to the transition row of the Periodic Table that, when

undergoing d-d electronic transitions, absorb characteristic frequencies of the visible light spectrum. Concerning opaque vitreous glass and vitreous mosaic tesserae, the color and opaque effects were obtained by means of many different substances (i.e., calcium and lead antimonates, lead stannate, tin oxide, quartz, wollastonite, metallic clusters), depending on the age and on the desired effects. In particular, regarding ancient red glass, color and opacity are generally ascribed to the presence of copper of different speciations (metallic clusters, or cuprite dendritic aggregates, or cations incorporated in the glass matrix).

Another ubiquitous element in archaeological and artistic glass is iron. It is typically present at levels that can impart, when in the reduced form, a well-known green coloration. To minimize this problem and to obtain transparent uncolored glass, from around the middle of the first millennium BCE, substances were added which tended to neutralize the effects of iron and/or to confer different colors. The main decolorant used before the Roman period was antimony oxide, while, from the second century BCE, manganese oxide was more frequently used. The coloring and decoloring roles of Fe^{2+} and Mn^{4+} , respectively, and their redox interactions during glass production, is central to a number of studies performed by XAFS. For instance, the Fe and Mn K-edge XANES spectra of a suite of transparent fragments of perfume bottles of the second century CE from Patti Villa, Sicily, were recorded. All finds contain both iron and abundant manganese, with the exception of one sample, characterized by a bottle-green color, which is lacking in manganese. The detailed analysis of the XANES features and of the pre-edge peak structure of the samples and a series of reference compounds revealed that, in the uncolored ancient glasses, iron is always present mainly as Fe^{3+} , while manganese is present in the reduced form Mn^{2+} , validating the hypothesis of a redox interaction between iron and manganese ($\text{Fe}^{2+} + \text{Mn}^{4+} \rightarrow \text{Fe}^{3+} + \text{Mn}^{2+}$), as a result of a deliberate addition of pyrolusite as a decolorant during the melting procedure.

In studies on historical glass and archaeological glass, the problems related to *weathering* are of paramount interest. They are faced by means of XAFS, especially on stained and buried glass. Stained glass, like for instance ancient cathedral windows, have been exposed for many centuries

to open air, atmospheric particulates from urban environments (diesel particles, dusts enriched in sulfates from combustion of wood, coal, candles), mold (when water condenses) as well as oceanic salts when they are exposed to coastal influences. Archaeological glasses are usually found buried in sepulchres (or in sunk vessels) and are exposed to chemical and microbiological interactions in soils or corrosive seawater.

Information on these artifacts is then essential to curators in order to conserve them. One of the first investigations on stained weathered glass windows was that on the St Gatien cathedral in Tours, France (thirteenth to fifteenth centuries). This cathedral is exposed to the oceanic climate from the Gulf Stream, and its stained glass windows (fourteenth century) show light brown corrosion cupules on the glass surface oriented to the inside, whereas thick, weathered white-greenish layers are visible on the outside surface exposed to atmospheric agents. In cross-section, these glasses consist of a 500 μm -thick layer composed of micron-thick layers of deep red and pale-green glasses. But the thin red layer is so intense in color that it gives its red color to the whole glass. Cu K-edge μ -XANES and EXAFS experiments have shown that the red color for some of these glasses is due to metallic copper nanoparticles (see NANOARCHAEOLOGY). In contrast, Cu is divalent in the weathered pale brownish-greenish crusts, with a local structure similar to that for chalcantite ($\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$).

A further proof of the importance of XAFS in cleaning and restoration interventions is provided by a study by Cagno et al. (2011) who, thanks to Mn K-edge μ XANES experiments, monitored the effect of a surface treatment of severely darkened birnessite-rich medieval glasses with a solution that solubilizes Mn(IV) into Mn(II). Negative side-effects of these treatments were revealed, including thinning of the glass upon crust removal.

Pigments and paintings

A large number of XAFS experiments focus on the speciation of archaeological and historical pigments and paintings, and on the characterization of their degradation reactions (Farges and Cotte 2016; Janssens et al. 2013).

Let us first discuss the interesting case of Paleolithic pigments. Since the discovery of cave rock art throughout Europe, several questions have been raised regarding the geographical and geological origins of the pigments used during the Paleolithic period, as well as the preparation and painting methods. The red color is systematically due to hematite ($\alpha\text{-Fe}_2\text{O}_3$), yellow to goethite ($\alpha\text{-FeOOH}$) or related ochre compounds and, finally, black to charcoal or manganese oxides/hydroxides. Chalmin and co-authors (2007) have identified various manganese oxides in black pigments, such as pyrolusite and romanechite, as well as other rare ones like manganite and groutite in various Paleolithic caves in Spain and France, including Lascaux. The use of XAFS in this study was needed because of the small size of the samples and because many samples were cryptocrystalline. Very interestingly, massive and fairly pure manganite was found in the cave of Combe-Saunière in the Dordogne, France. The sample, a sort of “crayon”, is thought to have served as a “pen” for the frescoes painted by those Paleolithic artists. Since this mineral is rare in nature and unknown in the areas where these paintings were realized, some trading routes must have existed to explain its presence in the Dordogne area.

Another important application of XAFS regards the *degradation phenomena* occurring in artistic pigments and paintings. Pigment degradation is usually a superficial phenomenon, where the major elemental composition remains unchanged, but where oxidation or reduction affects the chemical environment of elements, and consequently the color of pigments. μ XANES, which probes the element speciation with very good sensitivity and with submicrometric resolution, is particularly relevant for such analyses. Janssens and coworkers (2013) presented an exhaustive report of the μ XANES analysis of pigments over the last few years, and many other examples have been discussed by Farges and Cotte (2016) and Bertrand et al. (2012). For instance, XAFS has recently been used to study the fading of Prussian blue, the discoloration of smalt, the darkening of lead chromate in Van Gogh paintings, as well as in artificially aged model paintings. In this last case, it was shown

Figure 2 (a) An optical image of *Confuciusornis sanctus*. (b) Synchrotron rapid scanning X-ray fluorescence false-color images of the MGSF315 main slab. White: Cu; Black: Ca; Gray: Zn. (c) Radial distribution functions from EXAFS analysis at the Cu K edge of two standards compared with fossil feathers. The arrows in the copper oxide standard spectrum indicate features that are not present in the eumelanin standard. Modified after Wogelius et al. (2011), published by the American Association for the Advancement of Science.

that in both original and artificial painting fragments, pigment darkening was linked to the reduction of chromium from Cr(VI) to Cr(III).

Paleontological findings

The study of fossil remains and ancient human artifacts provides a wealth of information on ancient societies or cultural events and, more generally, can explain how systems or organisms adapted and evolved over time. One of the major problems encountered during the analysis of rare and ancient paleontological specimens derives from the fact that many analytical tools destroy at least part of the object under study. In this regard, micro-beam synchrotron-based techniques can be very powerful tools for non-destructive investigations.

In a recent study (Wogelius et al. 2011), synchrotron X-ray techniques—including XAFS—were applied to the study of fossils and extant organisms, including *Confuciusornis sanctus*, in order to map and characterize possible chemical residues of melanin pigments in extinct bird feathers. Figure 2a shows a visible light image of one of the *C. sanctus* specimens analyzed. Figure 2b presents the distribution of the key trace metals Cu, Ca, and Zn within this specimen as a false-color intensity map. The detail revealed in the distribution of Cu is striking, and

strongly implies that the Cu zoning is endogenous. Moreover, full EXAFS analysis of the Cu in the *C. sanctus* feather regions indicates that the element is organically bound, closely resembling the coordination environment found for Cu in natural melanin pigment (Figure 2c).

X-Ray Fluorescence Spectrometry (XRF)

M. STEVEN SHACKLEY

University of California, Berkeley, USA

X-ray fluorescence (XRF) is now a well-established method of analysis in both the laboratory and industry. The fact that the method is essentially nondestructive makes it particularly attractive for the analysis of archaeological and museum artifacts. Due to certain fundamental characteristics of the technique it is not suitable for some projects, which would seem at first sight to present no problems (Hall 1960).

Edward Hall's abstract for his 1960 paper entitled *X-Ray Fluorescent Analysis Applied to Archaeology* in the journal *Archaeometry* is just as appropriate more than half a century later. XRF spectrometry may be more "well established" but is still "not suitable for some projects," even though it might seem so and archaeologists might want XRF to be so. This section is dedicated to a brief discussion of the applicability of XRF analysis in archaeology.

How does XRF work and, more importantly, when and where is it appropriate? A number of recently published works delve into the subject in great depth and are highly recommended for further edification (summarized in Shackley 2011a).

Today, the market is being flooded with, it seems, hundreds of portable X-ray fluorescent (pXRF) instruments (see PORTABLE X-RAY FLUORESCENCE SPECTROMETRY (PXRF)), but do they really do all that the marketing suggests (Shackley 2011b)? Ioannis Liritzis and Nikolaos Zacharias provide a critical evaluation of pXRF in obsidian studies as well as other archaeological materials (Liritzis and Zacharias 2011). Is there a need anymore for the desktop/laboratory energy dispersive X-ray fluorescence spectrometry (ED-XRF)? Can we as archaeologists get away with only a much less expensive pXRF? Observing as an academic in a major university, upcoming students showed an increasing interest in pXRF as a solution to a

problem—is it a solution looking for a problem, or a very real need to be able to carry great analytical power into remote field conditions or museum settings? It may, indeed, be too soon to definitively answer these questions, but very recent newer versions of pXRF instruments and software may be resolving some of these issues.

The vast majority of archaeological XRF world-wide is applied to inorganic materials, mainly volcanic rocks (see ARCHAEOLOGY), and there are very good technical reasons for that (Shackley 2011a). This does not mean, of course, that there are not perfectly good reasons for analyzing ceramics or organics. While pottery is "not a rock," it is composed of rocks and clay sediments that lend themselves to XRF analysis. The very real difference is that unlike volcanic rocks as an example, they are not formed at very high temperatures in the mantle or crust, and may not necessarily be a reflection of human production.

What is very different from Hall's XRF world in the early 1960s is that archaeology as a discipline has changed markedly, both theoretically and methodologically, due in large part to the tools and technology that are offered in the twenty-first century. Issues of social identity, equality, gender, national character, and native rights are all current and important issues in archaeology today, and are being addressed with these new tools—XRF certainly among them (Joyce 2011). Scholars have argued elsewhere that without our twenty-first-century archaeological tools, a twenty-first-century archaeology would be not much more than the New Archaeology of the 1960s or culture historical in nature (Joyce 2011). XRF spectrometry will play an important role as a "well-established method" for illuminating our ever-changing problems in archaeology well into this century. What XRF will look like in another 50 years is impossible to imagine. The portables are probably a peep into that future.

History of XRF

X-rays were first discovered by the German physicist Wilhelm K. Röntgen (1845–1923), for

which he won the Nobel Prize in 1901. Charles G. Barkla in 1909 found a connection between X-rays radiating from a sample and the atomic weight of the sample. In 1913, Henry G. J. Moseley helped number the elements with the use of X-rays, by observing that the *K* line transitions in an X-ray spectrum moved the same amount each time the atomic number increased by one, a primary theoretical precept in XRF physics. He is credited with revising the periodic tables that were based on increasing atomic weight, to periodic tables based on atomic number. He later laid the foundation for identifying elements in X-ray spectroscopy by establishing a relationship between frequency (energy) and the atomic number, a basis of modern X-ray spectrometry. The potential of the technique was quickly realized, with half of the Nobel Prizes in physics awarded to developments in X-rays from 1914 to 1924. The early natural scientists could never conceive of the advances in XRF instrumental technology we enjoy today.

Principles of XRF

In ED-XRF analysis, samples are irradiated with high-energy photons from an X-ray tube or radio isotopic source. The primary X-ray beam excites electrons in the sample, causing it to emit secondary X-rays, that is, to *fluoresce* during a return of electrons to their orbits. The emitted X-rays occur at energies specific to elements in the sample, appearing as peaks over a given energy spectrum. The height or *intensity* of a given peak reflects, in part, the concentration of that element in the sample, and may be converted to units of concentration, usually by comparison to a regression line based on well-characterized standards after detection (Shackley 2011b).

Traditional destructive XRF analysis of geologic samples requires rigorous and time-consuming sample preparation. Samples are ground to a fine powder and pressed into briquettes, or for analysis of major elements to provide homogeneity, prepared as fused glass disks, particularly for wavelength XRF (W-XRF) where the relationship between the angle of the instrument and the object analyzed is crucial. However, with ED-XRF where the emitted

energy is captured by the detector for all elements simultaneously, and directed to a multichannel analyzer converting energy to pulses and ultimately through software to elemental data, the surface of the object is not as critical, and samples can be analyzed whole (Davis et al. 2011). While early ED-XRF instruments did not yield the instrumental precision of W-XRF, certainly neutron activation analysis (NAA) (see NEUTRON ACTIVATION ANALYSIS (NAA)) and advances in detector electronics and software have decreased the difference between these instruments and with miniaturization have heralded the pXRF emerging technology (Lirtizis and Zacharias 2011). A number of experiments (summarized in Davis et al. 2011) have shown that ED-XRF is *the* best technique in the analysis of volcanic rocks when sample destruction is not possible.

The overarching assumption seems to be that XRF, particularly ED-XRF, solves so many of our problems in geoarchaeology. Glascock (2011) addressed this issue by directly comparing the results of NAA with ED-XRF for obsidian sources (see CHERT, SILEX, AND OBSIDIAN SOURCING) of Mexico. See that study for an in-depth discussion on this subject.

What XRF can do

The appeal of X-ray analysis of archaeological specimens lies in its remarkable combination of practical and economic advantages:

- **Nondestructive:** In the vast majority of cases, analyzed samples are not destroyed or changed by exposure to X-rays. They can thus be saved for future reference or used for other types of testing that may be destructive, such as obsidian hydration analysis (see OBSIDIAN HYDRATION DATING).
- **Minimal preparation:** Many samples can be examined with little or no pre-treatment, including almost all obsidian artifacts. While it is best to wash any sediments off archaeological specimens, it has been shown that if the sediment is minimal, and the artifact has not been subjected to heat so high as to melt some sediment matrix onto the sample, vigorous cleaning is not necessary (Shackley and Dillian 2002). This is mainly due

to the penetration of X-rays in the mid-Z X-ray region beyond the surface, and while it does incorporate any contamination on the surface it is generally not an issue if some soil remains in the flake scars. The analyzed volume is very large compared to any surface contamination. This is not the case with most metals (see CHARACTERIZATION OF METALS AND ALLOYS), where patination and chemical weathering can radically change the composition at the surface and yield erroneous results (Hall 1960).

- Fast: X-ray spectrometry enables chemical compositions to be determined in seconds. For analysis of the elements Ti-Nb plus Pb and Th on the Berkeley Thermo desktop instrument at 100 live seconds per sample it takes about three to four minutes per sample to process, depending on mass.
- Easy to use: Modern instruments run under graphical interfacing software that easily handles measurement set-up and results calculation. Tasks that once required the constant attention of a trained analyst can now be handled by skilled students and are fully automated.
- Cost effective: Without the more involved sample preparation necessary in most W-XRF and all destructive analyses, the cost is significantly lowered per sample.

While this suggests that XRF will solve all our problems, it is not the all-knowing black box we would like it to be.

What nondestructive ED-XRF cannot do

- Sample size limits: Samples > 10 mm in smallest dimension and > 2 mm thick are optimal for ED-XRF analyses (Davis et al. 2011). Why is this important? Eerkens et al. (2007) noted that for hunter-gatherers in the North American West, high residential mobility often requires that stone sources, including obsidian, be conserved for long periods of time. As an example, an archaic hunter will attempt to rejuvenate a dart point rather than make a new one whenever possible as he or she moves through the landscape. The rejuvenation of that point creates debitage

that is quite small, often smaller than 10 mm. With modern recovery techniques, small debitage is recovered much more often than they were in the past, and to make a long story short, Eerkens et al. (2007) found that indeed these small obsidian flakes in Great Basin sites indicated not only greater distance to the original tool raw material, but also a greater diversity of sources than visible with analysis of the larger flakes with ED-XRF. So, while ED-XRF can analyze much of the stone material left in prehistory, it may not solve all problems of interest to twenty-first-century archaeologists. To be fair, however, the procurement ranges that could be reconstructed were relatively accurate with samples above the 10-mm threshold in the Eerkens et al. (2007) study, and NAA had to be used on the smaller flakes, which is essentially a destructive technique. Recently, however, with the newer digital ED-XRF instrumentation and tube collimation we have been able to reach sizes down to 2 mm with the Thermo Scientific Quant'X ED-XRF at Berkeley and Albuquerque.

- Restricted elemental acquisition: As discussed below, nondestructive XRF is restricted generally to a subset of the mid-Z X-ray region, and the best portion, including Ti-Nb, contains excellent incompatible elements for the analysis of volcanic rocks (Shackley 2011b). While some rare earth elements and those with low atomic numbers or with very low concentrations can be useful in discriminating sources, in most cases XRF cannot solve that problem. This is discussed in detail in Glascock's comparison between XRF and NAA (2011).
- XRF cannot characterize small components: XRF like NAA is a mass analysis—every component in the irradiated substance is included in the analysis. It is possible to collimate the incoming X-rays from the tube and/or into the detector to focus on small components such as various minerals, but environmental scanning electron microscopy (E-SEM), electron microprobe, or laser ablated inductively coupled plasma mass spectrometry (LA-ICP-MS) (see MASS SPECTROMETRY (MS)) is much better suited to this kind of analysis. However, the bulk

analysis of volcanic rocks has shown to be quite effective.

It is true that XRF will not solve all our problems in archaeological provenance studies; it is simply the best nondestructive analytical tool at our disposal at this time.

Is pXRF just the latest development in XRF?

While pXRF has both become very popular and been highly criticized, this is to be expected in a discipline that borrows much of its analytical technology (Liritzis and Zacharias 2011; Shackley 2011a, b). What seems to be most problematic is that these portable instruments were originally designed for mining and industrial applications seeking only qualitative results. This is not necessary and sufficient to address archaeological problems where relatively precise quantitative data are required. Tied to this, most of the instruments, unlike laboratory/desktop ED-XRF, did not allow the user to generate their own calibrations; indeed, most relied solely on fundamental parameter routines that are often standardless and could not be modified beyond factory settings. The criticisms have had their effect, and many of the manufacturers are generating software that allows the user to employ linear calibrations by ratioing peaks/counts to the Compton scatter and thus eliminate the problem of differing sample sizes, as earlier discussed by Davis et al. (2011) for laboratory ED-XRF instruments. Given these important shifts in the ability of pXRF, it will be possible to take a sensitive instrument to field or museum settings and nondestructively analyze at least volcanic rocks with similar instrumental precision and accuracy as laboratory XRF instruments. Most of the pXRF systems now available do not acquire the range of elements that laboratory systems do (i.e., Na through U), but the mid-Z (i.e., $Z = 19\text{--}41$) element sensitivity seems to be very good. There may come a time in the near future when portable systems will acquire the typical Na through U elements that laboratory instruments can today, but it is not here yet. This is likely the future of XRF in archaeology.

Hopefully, archaeologists will evaluate it with the same skepticism that is healthy for the discipline.

X-Ray Photoelectron Spectroscopy (XPS)

M. FANTAUZZI and A. ROSSI
Università degli Studi di Cagliari, Italy

X-ray photoelectron spectroscopy (XPS), also known in former times as electron spectroscopy for chemical analysis (ESCA), is one of the most popular surface analytical techniques applied to archaeology (see [ARCHAEOLOGY](#)) and archaeometry (see [ARCHAEOMETRY](#)). It is a surface-sensitive technique that provides the chemical state and composition within a sampling depth that might be estimated between 3 and 10 nm depending on the material and on the instrument geometry. Soft X-ray beams, usually Al K α (energy = 1486.6 eV) or Mg K α (energy = 1253.6 eV), are used as sources, the monochromatic Al K α source allowing the achievement of high-spatial resolution (down to 3 μ m) and high-energy resolution (0.45 eV).

If the sample size fits the XPS sample holder, no particular sample preparation is required and the sample can be analyzed in the as-received state. With modern spectrometers, many samples at once can be mounted on the platen. Analysis of powders and of low-vapor tension liquids is also possible. Sample treatments in situ include heating up to about 750 °C, cooling down to the liquid nitrogen temperature (ca. -170 °C), cleavage of minerals, and argon ion sputtering.

Since XPS is a surface-sensitive technique, the presence of an organic contamination layer, which might be quite thick in old artifacts, may mask the signals coming from the material underneath. In such cases it might be difficult to obtain the chemical information, and a surface cleaning procedure might be necessary either with solvents or by insitu Ar⁺ ion sputtering. If the Ar⁺ source conditions are set up in order to perform a “delicate” cleaning on selected small areas, the damage is limited and it might not even be visible to the naked eye. Sputtering may result in surface damage and thus may be adopted only

when there is no other method for analyzing the material.

Physical principles of XPS

XPS is based on the emission of photoelectrons from the atoms of a sample following interaction with soft X-rays having energy higher than the threshold electron energy of the emitting atoms. The photoelectrons are collected by a lens system and they are discriminated on the basis of their kinetic energy by the analyzer.

The experimentally measured kinetic energies (KE) of photoelectrons depend on the energy of the X-ray source ($h\nu$) and the binding energy (BE) of the electron in the atom according to the following equation:

$$KE = h\nu - BE - \Phi_s \quad (1)$$

where Φ_s is the spectrometer work function which is determined during calibration of the spectrometer. The electrons may arise from various core- and valence-band levels, the former being the most exploited in XPS.

Elemental and chemical state analysis

Elemental identification is achieved by comparing the BE values of the signals in the spectrum to those of calculated characteristic core- and valence-band electron levels or to local data-banks. The univocal assignment to a given element is based on the fact that the electrons are characterized by an energy state characteristic for each orbital of a given atom. Thus, the electron 1s of the carbon atom has a binding energy of 285.0 eV, while the electron 1s of the nitrogen has a binding energy of 400 eV, and that of the oxygen of 530.0 eV. It is worth emphasizing that two electrons in the same orbital have opposite spin and the electron energy is quantized.

The signals of the spectrum are labeled using the symbol of the element, followed by the energy level (n) and symbol of the orbital (l), so that

Figure 1 Survey spectrum of pure cellulose.

a signal labeled C 1s (Figure 1) means that an electron was ejected from the level, having $n = 1$, $l = 0$ (orbital s), of a carbon atom.

Elemental analysis is achievable by the so-called survey spectra, in which all the photoelectrons with binding energy values in a range usually between 0 and 1200 eV are displayed. The survey spectrum of pure cellulose is shown in Figure 1: C 1s, O 1s, and O 2p photoelectron peaks are detected together with the Auger signals C KLL and O KLL. The Auger electron signals are due to relaxation of the ions formed following emission of the photoelectrons. In the case of C1s, for example, as a consequence of the photoemission of an electron from the 1s level, a vacancy is formed. Carbon is thus unstable, and to lower its energy two phenomena may occur: (1) an electron from an upper level fills the core vacancy and an X-ray photon is emitted (X-ray fluorescence); (2) an electron from an upper level (e.g., 2p) fills the core vacancy and the energy gain involved in this transition allows the emission of a second electron from the 2p level named Auger electron, which contributes to the XPS spectrum. Following the X-ray notation, the Auger signal is labeled using the symbol of the

element followed by three capital letters (C KLL in the case of carbon Auger peak). The K letter indicates the level 1s, where the primary vacancy is formed as a consequence of photoemission ($K = 1s$); the first L indicates the level from which the electron from the upper level fills the primary vacancy ($L_{2,3} = 2p$) and the second L indicates the level from which the second electron (Auger electron) is emitted ($L_{2,3} = 2p$).

High-resolution spectra focus on a single element and are usually recorded with smaller step sizes and smaller binding energy ranges than surveys (see insert of Figure 1). Furthermore, BE values change when the same element is in different chemical states, that is, in different compounds; for this reason, valuable information on the chemical state of the elements can be obtained by XPS.

The Auger signals may be used also to obtain complementary information on the chemical state of the elements when the chemical shift is not high enough to allow its identification. The combined use of photoelectron and Auger signals in the chemical state plot is extremely useful for identifying the chemical state of the elements.

Quantitative analysis

Since peak intensity is related to the number of photo-emitting atoms, XPS also provides the quantitative composition, in atomic percentages of the elements present at the surface (e.g., table in Figure 1). In the case of homogeneous samples such as cellulose, a simple equation can be used for calculating the sample composition.

Very often, the sample surface of artifacts is not homogeneous in depth due to the presence of a surface film, for example, thin oxide layers, patina on metallic artifacts, or altered outermost layers of polymers or glass. In this case, cleaning by solvents might be applied; alternatively, argon ion sputtering can be performed in situ. More complex mathematical models for quantification might be considered also, and nondestructive in-depth profile as angle-resolved XPS (ARXPS) might be a useful resource in the case of thin layers (<10 nm).

Sputtering depth profile

The surface of the sample is cyclically Ar^+ sputtered. After each sputtering cycle the spectra are acquired and if the sputtering rate is known it is relatively easy to reconstruct the concentration versus depth profile. This technique should be avoided in heritage studies in order to preserve the artifacts. Furthermore, Ar^+ bombardment may induce changes in the subsurface region since only about 1 percent of the impact energy is used for sputtering. An example of the alteration induced by Ar^+ is reported in a study of the corrosion patina formed on bronze surface, where the authors (Squarcialupi et al. 2002) found the presence of copper sulfide in the patina, but they demonstrated that the presence of sulfide was due to the decomposition of CuSO_4 under ion bombardment.

Three-layer model

For samples whose surface comprises a thin oxide layer (surface film) on a metallic substrate, the three-layer model (Figure 2) is suitable to be used (Rossi, Elsener, and Spencer 2004). Each

of the layers, substrate, surface film, and contamination layer, is considered homogeneous in thickness and composition. Photoelectrons from the metallic substrate are attenuated by the oxide and by the contamination layer; photoelectrons from the oxide layer are attenuated only by the contamination layer. Based on a single XPS measurement, the three-layer model allows determining the thickness of both the oxide (t) and the contamination layers (l_c) and the composition of the oxide and of the interface beneath that might differ from the bulk composition (Figure 2). This model has been successfully applied to historical brass wind instruments, to study the thickness and the composition of the oxide layer formed upon contact of brass alloys with saliva.

ARXPS in-depth composition profile

An alternative way to obtain information about the in-depth distribution of elements in nonhomogeneous nanometric-thick layers requires acquisition of the spectra at different emission angles, in a so-called angle-resolved XPS (ARXPS) experiment. Since the sampling depth is related to the emission angle, spectra acquired at different emission angles provide the composition at different depths. To obtain the in-depth composition profile from the composition versus angle experimental results, algorithms have to be applied to the experimental data (Rossi et al. 2004).

Another model that allows reconstructing depth profiles was developed by Tougaard and provides a quantitative estimate of atoms in depth distribution within the outermost surface region, but requires spectra acquisition of highly pure reference compounds to simulate the sample spectrum: With this model, a few model structures can be verified and a maximum of six structural parameters can be determined.

Examples of XPS applications

Pottery

Several studies are reported in the literature on XPS characterization of pottery (see ELEMENTAL ANALYSIS OF POTTERY). These studies involve surface characterization with different

Figure 2 Three-layer model.

purposes: for example, provenance studies, conservation/deterioration studies, investigations on color and chemical state of the elements, and researches aimed at improving the knowledge of the technological skills of potters.

XPS was exploited to gain information about the provenance of pottery by means of the (Al+Fe)/Si ratios obtained by XPS quantitative analysis.

In a multi-technique study by Casaletto and colleagues (2006) the authors characterized the conservation state of medieval pottery from Caltagirone (Sicily, Italy) in order to identify the possible causes of alteration and/or degradation phenomena for both the ceramic body and the polychromatic glaze of the artifacts. Based on XPS analysis, the authors provide evidence of the presence of a carbonate-bearing, protective layer

on the surface of the glazes. The carbonate content decreased in the partially deteriorated samples, exposing lead, which was typically present in Islamic ceramics. A comparison between the surface and the bulk composition (achieved by energy dispersive X-ray (EDS) analysis) allowed the authors to observe devitrification phenomena at the surface and alkali depletion.

The roles of iron and manganese oxides in red, brown, and black decorated shards of pre-Roman pottery from southern Italy (Canosa) were examined by XPS by Sabbatini et al. (2000).

Ancient glass

XPS was used as a complementary technique in multi-analytical study applied to ancient glass characterization. Due to the high surface sensitivity, it allowed the investigation of the surface deterioration of glasses due to weathering. Furthermore, XPS was exploited for determining the chemical composition and identifying the chromophores of colored glasses (see GLASS COLOR), providing the chemical state of the elements and helping in shedding light on the knowledge of ancient glass-makers (Angelini et al. 2004). The effect of cleaning treatments of glass surfaces was also studied by XPS, indicating that the use of chelating agents to remove encrustations from corrosion processes has to be avoided.

Metals and alloys

Most of the work on XPS application to metals and alloys (see CHARACTERIZATION OF METALS AND ALLOYS) of historical interest is devoted to study the composition of the patinas on bronzes and brasses. The sacrificial role of tin in bronze that prevented copper oxidation and the formation of “white lead” $[2\text{PbCO}_3 \cdot \text{Pb}(\text{OH})_2]$ at the surface of Roman leaded brasses of the third century BCE were demonstrated by Paparazzo and Moretto (1995). XPS was also exploited for calibration purposes of miniaturized optical sensors for nondestructive, in-situ analysis of patinated bronze and copper: The XPS experiments, carried out at liquid nitrogen temperature to prevent damage of the patina, allowed distinguishing among brochantite $(\text{Cu}_4(\text{OH})_6\text{SO}_4)$ and

antlerite $(\text{Cu}_3(\text{OH})_4\text{SO}_4)$ which are the principal corrosion products on copper and bronze upon exposure to urban and industrial atmosphere, and chalcantite $(\text{CuSO}_4 \cdot 5\text{H}_2\text{O})$ which is an indicator of the degradation of the protective patina due to acid rain and fog (Schlesinger, Klewe-Nebenius, and Bruns 2000). Similarly, XPS was used for the “calibration” of a miniaturized nondestructive electrochemical sensor used to monitor in situ the corrosion state of historical brass wind instruments: In this context, XPS information on both model alloys having the same composition of brasses used during the nineteenth century and on real specimens was related to the electrochemical response of the electrode, thus giving the possibility of obtaining the chemical composition from open-circuit potential and polarization resistance measurements. Such studies allowed observing the formation of a protective film mainly composed of CuSCN and $\text{Zn}_3(\text{PO}_4)_2$ upon contact between brasses and artificial saliva (Cocco et al. 2016).

Paper and writing supports

Despite the potentialities of XPS in detecting the surface qualitative and quantitative composition of artifacts of historical interest, few studies dealing with XPS applied to ancient papers (see PAPER ANALYSIS) have been published. In Righini et al. (1998), the deterioration of ancient papers produced in Europe between the fifteenth and eighteenth centuries is reported. According to the authors, the use of gelatin in the sizing process and the addition of calcium carbonate during paper production influenced the conservation state. The N/C and Ca/C ratios determined by XPS analyses allowed distinguishing among papers differently conserved, and the results showed that the higher those ratios, the better preserved the papers.

X-Ray Radiography

MARIA PIA MORIGI

University of Bologna, Italy

X-ray radiography is an imaging technique widely applied in the field of heritage since the discovery of X-rays by the German physicist W. C. Röntgen in 1895. In fact, even before the establishment of radiology as a medical specialty, radiological examinations were performed for studying mummies and other archaeological finds. In March 1896, Walter Koenig, a lecturer at the Physical Society in Frankfurt, published a monograph reporting on the radiographs of the knees of an Egyptian child mummy and the upper part of a cat mummy. A paper published by Culin two years later describes the work carried out in 1897 by Charles Leonard to produce radiographs of a Mochica mummy and other artifacts from the University of Pennsylvania Museum. Prior to this, in order to gain knowledge or simply to satisfy curiosity, many mummies had been unwrapped, suffering damage and in some cases even total destruction in the process. Koenig also made the first so-called “shadowgraphs” of paintings. X-rays were occasionally used to reveal forgeries or hidden signatures, but generally speaking, before World War I there was no systematic application of X-ray radiography to the study of paintings. A turning point occurred in 1925, when Alan Burroughs embarked on an extensive research project at the Fogg Art Museum in Harvard, with the aim of creating an archive of X-ray shadowgraphs. After purchasing X-ray equipment, Burroughs visited numerous museums in the US and Europe, collecting radiographs of famous paintings of mainly Italian, Dutch, and Flemish Masters. The “expeditions” of Burroughs renewed interest in the use of radiography, leading to the setup of X-ray labs in several American and European museums.

Today, radiography is increasingly being used in the study of archaeological finds and

works of art. It is a non-destructive technique, capable of providing insight into the internal structure of objects, by revealing features and details that would otherwise be invisible. Radiography can help scientists to answer many questions about the constituent materials, manufacturing techniques, and functions of an object; it is a useful and sometimes essential resource for restorers and conservators also, as it can reveal cracks, corrosion, and previous restoration work.

Physical basis of X-ray radiography

X-rays are a form of high-energy electromagnetic radiation, produced when fast-moving electrons interact with matter. X-rays are commonly characterized by their energy (E) or by their wavelength (λ) and frequency (ν). These properties are related by the following expression:

$$E = \frac{hc}{\lambda} = h\nu \quad (1)$$

where h is Planck's constant and c is the speed of light in a vacuum.

The physical principle on which radiography is based is the differential absorption of X-rays (see X-RAY ABSORPTION SPECTROSCOPY (XAS, EXAFS, XANES)) as they pass through matter, as this is responsible for the contrast in images. In a typical setup, the radiation is emitted by a source and detected by an appropriate detector after interaction with the object studied (Figure 1). Various interaction phenomena (photoelectric absorption, Rayleigh and Compton scattering, production of secondary radiation) may occur with different probabilities depending on the energy of the radiation and the nature of the materials making up the object. Consequently, the intensity of an X-ray beam decreases as it travels through matter. The Beer-Lambert law describes the attenuation of a monochromatic X-ray beam produced by a homogeneous material:

$$I(x) = I_0 e^{-\mu x} \quad (2)$$

where $I(x)$ is the intensity of the radiation transmitted, I_0 is the intensity of the incident radiation, x is the thickness of the material, and μ is the linear attenuation coefficient (in units of cm^{-1}), which depends on the atomic number and density of the material and on the X-ray energy.

Generally speaking, elements with high density and high atomic number absorb X-rays more than lighter elements. For example, in the radiography of paintings, metal nails or dowels, and pigments such as vermilion and lead white, which contain heavy elements (mercury and lead, respectively), will produce a good radiographic contrast with canvas or wood.

X-ray sources

The X-ray source most frequently used for the radiography of cultural objects is the X-ray tube, which is a high-vacuum tube inside which a heated filament in the cathode produces a steady stream of electrons. The potential applied between the cathode and the anode accelerates the electrons toward the target, where most of their kinetic energy is converted into heat (typically around 99%), and the remaining fraction into X-rays. The spectrum of X-rays obtained is the sum of two components: the characteristic or line spectrum of discrete energies, and the continuous or “white” spectrum, also known as *Bremsstrahlung* (or braking) radiation. The intensity and penetration power of the X-ray beam can

be changed by varying the cathode current (mA) and tube voltage (kV). In particular, increasing the current will increase the number of the X-rays produced, but not their energy, while increasing the potential will increase both the maximum energy and overall intensity of the X-ray beam.

Due to the great variety in size, density, and materials typical of heritage assets, different X-ray sources must be used in order to obtain optimal results (Casali 2006); in particular, a crucial factor is the selection of the energy most appropriate for the thickness and nature of the material. For example, the radiographic examination of paintings and low-density materials, such as paper and textiles, requires the use of soft X-rays with energies lower than 30–40 keV. The great majority of radiographic studies in the heritage field have been conducted using laboratory or transportable setups with X-ray tubes of up to 200 kV; however, in the case of large artifacts and metal or stone objects of considerable thickness, a highly penetrating, high-power radiation source is required. Most frequently, orthovoltage X-ray tubes, developed for nondestructive testing in the industrial field, are used, but radiographs of bronze or marble statues have been obtained using γ -ray sources in the past (mainly ^{60}Co and ^{192}Ir). More powerful setups (betatrons and linear accelerators) exist, but their application in the field of heritage study and diagnostics is still limited.

Detectors for analog and digital radiography

The differential X-ray absorption by the object studied produces some local changes in the intensity of the transmitted radiation which give rise to the so-called “primary radiological image”. Since the human eye is insensitive to X-rays, this image must be converted into a visible one by means of a suitable detector. Photographic films have been used for this purpose for decades, but nowadays they are being increasingly replaced by a variety of detectors for digital radiography, such as photostimulable phosphor plates, fluorescent screens with charge-coupled device cameras, and flat panel detectors. Today, X-ray films still have better spatial resolution (about 10 μm) than phosphor imaging plates and other digital detectors (40–200 μm); their limited dynamic range, however, often requires testing exposures to determine the best combination of acquisition parameters (voltage, current, and exposure time) (Alfeld and Broekaert 2013). Moreover, when a wide range of radiographic densities is present in the investigated artifact, it might be necessary to take images at different X-ray energies. Otherwise, with a digital detector, a single exposure is usually sufficient, thanks to its high dynamic range, as well as the possibility of optimizing the visible gray levels in the image. Other advantages of digital detectors include a lower dose, no need for chemical reagents, real-time response, and image access from remote locations.

Examples of application of X-ray radiography to cultural material

Radiography is a versatile imaging tool: most materials, including ceramics, stone, metal objects, and organic items, such as wood, textiles, and human remains, can be radiographed with satisfactory results. A broad overview of the application of radiography to different kinds of cultural materials can be found in Lang and Middleton (2005).

For example, as previously stated, X-rays have been used since their discovery to investigate ancient mummified bodies for different

purposes: the study of embalming techniques, search for jewelry and amulets in Egyptian mummy wrappings, determination of age and sex, detection of diseases and physical traumas, and identification of fakes and forgeries (Chhem and Brothwell 2008).

The analysis of soil blocks from excavations is another interesting application of radiography in archaeology. In fact, particularly fragile and complex finds or assemblages of objects are not recovered on-site, but are often lifted together with the block of surrounding soil in order to allow safe transport to the laboratory and then subject to careful micro-excavation in a controlled environment. Radiography is invaluable in the clarification and location of the contents of a soil block when laboratory excavation is performed (Shearman and Dove 2005): it helps to preserve even the smallest fragments of the object, as well as delicate materials such as textile remains. For example, Figure 2 shows a picture and two radiographs, viewed from different angles, of a soil block ($40 \times 15 \times 10 \text{ cm}^3$) extracted in the necropolis of Villalfonsina, discovered in the province of Chieti (Abruzzo, Italy) and probably dating back to the sixth to fourth centuries BCE (Re et al. 2015). The radiographs reveal the presence of a fragmented bronze belt that was placed around the body of the deceased.

Archaeological investigations frequently bring to light numerous metal finds. These can be X-rayed as part of the post-excavation procedures to assist in determining the function of the finds and the method of manufacture. In fact, the identification of an object is not always immediately obvious if it is covered with corrosion products, as is frequently the case with excavated ferrous material as a result of their burial. In this case, X-ray radiography can contribute to the characterization, technical description, classification, and dating of metal artifacts (see CHARACTERIZATION OF METALS AND ALLOYS). For example, ancient coins with surface details obscured by accretions can be identified by radiography in some instances. In addition, the radiography of metalwork provides a long-term visual record of unstable and potentially deteriorating artifacts.

Pottery is another material frequently found in archaeological excavations. The radiography

Figure 2 A picture (a) and two radiographs (b–c) viewed from different angles of a soil block extracted from the necropolis of Villalfonsina (Abruzzo, Italy), dating back to the sixth to fourth centuries BCE. The radiographs reveal the presence of a fragmented bronze belt. From Re, A., J. Corsi, M. Demmelbauer, et al. (2015). “X-Ray Tomography of a Soil Block: A Useful Tool for the Restoration of Archaeological Finds.” *Heritage Science* 3: 4–10; Springer Open Access article distributed under the terms of the Creative Commons Attribution License: <http://creativecommons.org/licenses/by/4.0>.

of ceramics (see X-RADIOGRAPHY AND CERAMICS) may be useful mainly for two purposes: characterization of the clay fabrics, and investigation of shaping and fabrication techniques (Carr 1990; Berg 2008). Unlike modern ceramics, archaeological pottery was commonly made from clay pastes containing coarse, aplastic inclusions that may have been either intrinsic to the clay or added, as tempers, by the manufacturer for various reasons. Even though the contrast is generally limited, radiography is able to visualize the size and shape of aplastic inclusions, as well as the voids left by organic matters (e.g., chopped grass or chaff) burned out during the firing of the pottery. This information can be useful for characterizing clay pastes derived from particular sources or prepared in special ways. Radiography can also be helpful for other aspects of the study of ceramics: for example, it may reveal old breaks and repairs, show the contents of still-sealed vessels, and unmask fakes.

Lastly, another common application is the X-ray examination of paintings, which is able to provide us with information on many aspects, such as:

- the state of conservation of both the paint layer and the support;
- the possible existence of changes in the paint layer (the so-called “pentimenti”) and/or underlying paintings;
- the presence of previous restoration work;
- the painting technique of a certain artist;
- the authenticity of a work of art.

In examining items of archaeological interest, X-ray and neutron-based imaging techniques (see NEUTRON RADIOGRAPHY AND TOMOGRAPHY) may provide interesting complementary information, especially when the examined object has a composite structure made of metal and organic materials. In fact, unlike for X-rays,

neutrons are attenuated by some light elements (e.g., H, Li, B), for which X-rays do not provide a good contrast, whereas they easily penetrate thick layers of metals like Pb, Fe, and Cu, where standard X-ray imaging would fail.

Sometimes radiographic images are difficult to interpret because of an important limit of radiography: the superimposition of features belonging to different layers of the object. In fact, in conventional radiography, a three-dimensional subject is projected onto a two-dimensional detector; therefore, information with respect to the third dimension (depth) is lost and each point of the resulting image provides a measure of the overall attenuation of the X-ray beam as it passes through the object. This limitation has normally been overcome by taking radiographs from different angles or by using X-ray stereoradiography, a technique based on the acquisition of two radiographs from slightly different viewpoints; their viewing through an appropriate apparatus gives a 3D image. In addition to the application in medicine, stereoradiography has also been applied to cultural materials, being particularly useful for ceramics, human remains, and wooden statues (Lang and Middleton 2005). Stereoradiography, however, has become essentially obsolete after the introduction of computed tomography (CT) in the early 1970s. This technique is able to provide a 3D reconstruction of the inner structure of the objects studied, while preserving their integrity. Even though CT is primarily used as a diagnostic tool in the medical field, in recent years its importance and potential when applied to cultural materials has become increasingly apparent. After its first use for the examination of mummified human and animal remains (see, for example, Hoffman, Torres, and Randy 2002), a growing number of authors have reported the successful use of CT in the study of archaeological finds and works of art; it can be therefore expected that the application of this technique will increase further in the future.

X-Ray Tomography

FRANCO CASALI

Academy of Science of Bologna, Italy

In order to study, restore, and better preserve archaeological finds, several non-invasive diagnostic techniques are being used with increasing frequency. Among these, CAT scanning (computer-aided tomography, also called CT: computed tomography), routinely used in medical diagnosis, is playing an important role in obtaining detailed views of objects of antiquity (see COMPUTED TOMOGRAPHY). The result of a CT scan is a 3D volumetric image that contains information on the structure and composition of objects and assemblies. The input data for the 3D inspection image is a set of radiographic transmission images acquired at different angles with respect to the source–detector beamline. Usually the object is rotated 360° with small angular steps. If 0.5° rotation steps are used, 720 digital images are obtained. If the object cannot be moved, the acquisition system (radiation source and detector) rotates around it. These images, processed with suitable mathematical algorithms, make it possible to reconstruct the different internal structures of the object/assembly.

The object is “virtually” rebuilt by bringing together the various sections into a single volume. Further processing, such as “virtual volume cuts,” can reveal many internal details. The CT image is composed of many small volume elements—called *voxels*—as with LEGO™ construction toys. The smaller and more numerous the voxels are, the higher the image definition. Spatial resolution for CT inspection images can be quite small, but this impacts both the field of view for the scanning and certain requirements for the data acquisition. The result is that for high-fidelity 3D CT inspections, several thousand radiographs may be acquired (Brancaccio et al. 2011).

Instrumentation

The equipment for CT acquisitions consists of five components: (a) the radiation source to be used (X-rays, gamma rays, or neutrons); (b) an acquisition system for the digital radiographic transmission images produced by the interaction between the object and the source (i.e., scintillators coupled to amorphous silicon arrays, CMOS arrays, cameras or linear diode arrays); (c) a rotating platform upon which the object to be inspected is situated, or a mechanical system (source plus detector) that rotates around the object, as in a medical CT; (d) a computer to manage the image acquisition (object handling, operation of the source and the system); and (e) a computing system able to provide the image “virtually” reconstructed, even at a later time.

Acquiring high-quality CT inspection data requires the choice of several key parameters for scanning, and each choice can involve “trade-offs”. The type of penetrating radiation and the energy selected is fundamental: if the radiation is too weak (from the energy standpoint), it does not pass through the object; if it is too strong it is not attenuated enough and therefore does not yield information. A physical analysis of the thickness and composition of materials can point to an “optimum” radiation energy (sometimes a couple of choices emerge for gamma-rays, X-rays or neutrons). CT inspections at low to medium energies can be non-invasive, but some effects on the object occur for higher energies (for instance, color changes in the material, or activation from high-dose rates).

For the analysis of objects in the archaeological field, we can subdivide the tomographic systems with photon sources into three classes: (1) high spatial resolution systems (micro- and nano-CT) with low voltage sources, which are mainly used for small items; (2) systems for objects of mean size and not-too-high density, with X-ray sources with a 200–600 kV voltage; (3) systems with

Figure 1 A mock-up of an ancient treasure (a clay cup with some bronze coins) inspected by X-ray CT. Reproduced with permission from: Berdondini, A., R. Brancaccio, V. D’Errico, A. Miceli, M. Bettuzzi, F. Casali, M. P. Morigi, M. Senn, and A. Flisch (2011) “The Use of Industrial Computed Tomography in the Study of Archaeological Finds.” *Proceedings of the 37th International Symposium on Archaeometry*, edited by I. Turbanti-Memmi, 575–78; Springer-Verlag.

high voltage sources (greater than 1000 kV), called LINACs (linear accelerators), which are able to scan large-size and high-density finds; (4) radioisotopic sources that emit photons with energy greater than 1 MeV.

Up until a few years ago, high-energy sources were radioisotopic sources (mainly Co-60 and Ir-192). These sources are still used for some industrial applications. Their advantages include low cost and portability, but the disadvantages include “larger focal spots” (problematic for obtaining better spatial resolution), and comparatively low intensity. In addition, the transportation of radioactive sources outside of shielded and controlled environments is much

more dangerous. Machine sources (X-ray tubes and LINACs) are higher output, include smaller focal spots, and can be fully interlocked for safe operation.

LINACs are commonly used in industrial inspections as a source of high-energy X-rays (2–15 MeV). In this modality, accelerated electrons impinge on metal plates (usually copper or tungsten), thus giving rise to the “radiation of *Bremsstrahlung*” (X-rays). Recently, some small electron accelerators, called *betatrons*, have been used in field-portable systems for inspecting infrastructure objects (Martz et al. 2016) using MeV energies (up to 8 MeV). While both LINACs and betatrons have been used

in “object-stationary” systems, betatrons are smaller and more portable. (For an example of a portable betatron, see <http://www.globalxray.com/industrial-radiography/>) In the future, these machines will be of great interest for inspecting objects that cannot be transported to the laboratory (statues, columns, excavation blocks, and so on).

High spatial resolution tomographies can be obtained by micro-CT systems. In this case, the source of X-rays, a micro-focus tube, can include focal spots of 5–100 microns and a 1–500 μA current. The spatial resolution is in the 10–20 micron range. To obtain higher spatial resolutions, one can use a *nano-focus* source where the focal spot is around several hundred nanometers. Accordingly, the output current of this source is very weak (usually less than 100 μA) and the system can only be used to analyze either very small objects or low-attenuation materials.

While most machine X-ray sources are poly-energetic, single-energy sources are available. A single-energy source can acquire the most quantitative radiographic data that does not include some of the artifacts common to poly-energetic source (i.e., beam hardening). CT scans can be acquired at the “optimum” energy, or perhaps at a number of single energies, and the scans taken together can be used to perform detailed materials characterization (Martz et al. 2016). Third-generation “synchrotrons” include the ability to scan a single-energy over a significant range (up to 100 keV) (see SYNCHROTRON-BASED X-RAY ANALYTICAL TECHNIQUES AND MATERIALS ANALYSIS). Synchrotrons also provide an opportunity for “phase-contrast” inspections, a powerful high spatial resolution modality for low energy (Gerlach et al. 2006).

Micro- and phase-contrast CT in archaeology

Micro-CT applications in archaeology extend to parts of ancient human bodies, mainly bones and teeth (see BONES AND IVORY) that can be studied “non-destructively”. By using a micro-CT, it was possible to show that, out of 11 human teeth discovered in a Neolithic graveyard in Pakistan, dating back 7,500–9,000 years, nine showed they had received dental treatment in vivo (Coppa

et al. 2006). Further, the analysis of bones, small metal objects, jewelry, and ceramics can be conducted successfully with a micro-CT (Sanger et al. 2013), also uncovering details about life in the ancient past.

Over the past 15 years, the progress made in phase-contrast imaging has made it possible to study compounds of similar objects and low-density materials. A striking example is provided by the study of some carbonized papyri from Herculaneum (Italy), in the so-called “Villa dei Papiri” which, in 79 CE, caught fire due to the eruption of Vesuvius. Six of these papyri belong to the collection of the Institut de France. Two of these (one unrolled and one still rolled) were recently analyzed at the European Synchrotron Radiation Facility (ESRF) in Grenoble, France, in the “biomedical beamline ID17” line. The phase contrast between the ink (coal-based and with a thickness of about 100 microns) and papyrus fibers was sufficient to “read” some sentences written inside the roll (Mocella et al. 2015).

Medium- and high-energy X-ray CT

Average-energy systems (100–450 kV) are those most used in diagnostics for archaeometry because they are easily transportable and fairly low cost.

Within the framework of the European Project DETECT at EMPA—the Swiss Federal Laboratories for Materials Science and Technology (Dübendorf)—CT equipment has been developed, mainly for industrial applications. It has a 450 kV X-ray source and a digital camera detector coupled with a 45×32 cm CsI screen. In order also to assess its application in the field of archaeology, a mock-up of an ancient treasure (a clay cup with some bronze coins) was inspected with X-ray CT (see Figure 1). The resolution is sufficient to read the inscriptions on the coins (Berdondini et al. 2011). In the case of a cup full of ancient coins, the voltage of 450 kV is no longer sufficient and higher-energy sources must be used.

A recent and informative CT scan of a pot full of Roman coins (Miles et al. 2016) was performed by a collaboration between archaeologists and scientists at the British Museum in London, and the University of Southampton, UK, using

MeV energies (see <https://www.theguardian.com/science/2012/jul/09/x-rays-reveal-secrets-roman-coins>).

Ancient bronze artifacts (cups, statues, and so on) are very thin (a few millimeters of metal), as can be seen from a 3D CT of an old Roman bronze statue of Eros (Figure 2) (Bettuzzi et al. 2015). This CT scan was performed at the Getty Conservation Institute (USA) using equipment similar to that developed at EMPA. Unlike ancient bronzes, Renaissance materials can be about one or two centimeters thick. From the CT inspection data, it is possible to identify the casting period of a bronze statue and the technique of casting.

All of these inspections were performed with sources that are not easily transportable and must be used either in bunkers or in specially equipped mobile containers. At the same time, important archaeological discoveries are often

made in inaccessible areas, especially in Africa. In such areas, there are usually no facilities equipped with tomographic systems capable of scanning objects at the target spatial resolution. In these cases, lacking a good CT system in the immediate vicinity, it is necessary to move modern CT equipment to the site. An example of this approach is the CT image of the skull of “Lady Buya”, a prehistoric hominid who lived about one million years ago, found in Danakil (Eritrea) by a joint delegation from the University of Rome and the Pigorini Museum of Rome (Italy). This skull, which is still preserved at the Museum of Asmara, was first scanned with old CT equipment at the local hospital. Since this type of analysis was very important for paleoanthropology reasons (brain volume, etc.), the Department of Physics of Bologna was asked to bring an appropriate tomographic system to Asmara. Even though the local

Figure 2 X-ray CT image of a Roman bronze statue of Eros performed at the Getty Conservation Institute (Los Angeles, USA). From the images it is possible to see how thin the bronze is. Reproduced with permission from: Bettuzzi, M., F. Casali, R. Brancaccio, M. P. Morigi, D. Carson, G. Chiari, and J. Maish (2015) “Computed Tomography of a Medium Size Roman Bronze Statue of Cupid.” *Applied Physics A* 118 (4): 1161–69; Springer.

environmental conditions were not the best, the high-quality system components (200 kV micro-focus X-ray tube and a 40 × 50 cm scintillating screen) meant that results exceeded expectations.

Blocks of soil

Many museum warehouses all over the world hold blocks of soil extracted during excavation campaigns that may contain metal objects of archaeological interest. The extraction of possible finds is expensive and time-consuming (weeks or months). This investment is justified only if the block of soil contains something interesting from an archaeological standpoint. However, sifting the soil in an intrusive way can destroy key evidence in the soil (packing patterns, and evidence of water paths). The type of block determines the characteristics of the X-ray source. The bigger the block dimensions, the higher the required energy of the photons for a robust detected signal. This is an opportunity for 3D CT, a high-quality 3D image of an object contained in any block of soil, which can be then reproduced using modern 3D printing techniques and an appropriate metal material. There are several papers on the CT of “blocks of soil”. At EMPA, researchers studied an excavation block (ca. 100 BCE) with Celtic material inside. The source was a transportable LINAC, with energy of 4 and 6 MeV, capable of operating for several days without interruption—properties that make it particularly suitable for that kind of work (Flisch et al. 2014).

Neutron tomography

In some circumstances, neutrons provide a better alternative for the inspection of hydrogen-rich materials in large structures. While photons mostly interact with the electronic structure of matter, neutrons—particles with no electrical charge—interact with the nuclear structure. The most important interactions of neutrons are “scattering” (interaction with elastic and inelastic collisions), absorption (with subsequent emission of other particles and/or photons), and the fission of particularly heavy nuclei (uranium, plutonium, etc.). Lightweight elements (such as hydrogen,

deuterium, carbon, and oxygen) remove neutrons from the beam through the scattering process.

Other elements (such as boron, copper, and cadmium) remove neutrons from the beam through the nuclear absorption process. Consider a recent study (Mannes et al. 2015) where the same object was inspected with X-rays and neutrons (see NEUTRON RADIOGRAPHY AND TOMOGRAPHY). The radiographic images obtained with the two radiations were very different from each other. A lead object is almost transparent to neutron radiation and opaque to X-rays; the opposite is true for organic materials (cloth, wood, biological tissue, etc.), which are opaque to neutron radiation and almost transparent to X-rays. The two sets of information are complementary, especially when the object under examination is made of both organic material and metal (see NEUTRON IMAGING AND TOMOGRAPHY IN CONSERVATION AND NEUTRON RADIOGRAPHY AND TOMOGRAPHY).

Scanning with both types of radiation is a powerful inspection tool. There are very few research centers in the world that are able to perform both tests of an object in sequence. One of these is the Helmholtz-Zentrum Berlin für Materialien und Energie in Berlin, Germany. Interesting measurements of different objects have been performed with the two radiation sources. The neutrons for experiments were produced in the CONRAD line, which is connected to the BER-II research reactor. As an X-ray source, a micro-focus tube was used.

Another important laboratory for this kind of measurement is the Paul Scherrer Institute in Switzerland (PSI: <https://www.psi.ch/>). Neutron tomography can also be performed by mobile neutron sources, but with poorer results due to the weak neutron output. One side-effect for neutrons is that acquiring high-quality CT requires long scan times; the result is that any object with some metal inside can remain radioactive for varying lengths of time, depending on the nuclear properties of the irradiated material. As a general rule, bronze objects must be kept away from the public for a few days.

CT for education

For archaeology, “dissemination science” specifically devoted to attracting the interest of young

people is very important. CT, which provides information on what we can find inside an object, is a great tool for this kind of knowledge. For students on a museum visit, it is one thing to have simply an uncritical view of a series of dusty Egyptian small mummies, but another to be able to see, through appropriate filmed simulations, what types of animals are contained in them and what their history was. In order to attract the attention of young visitors, at the Civic Museum of Bologna (in the Egyptian section), a screen has been placed near some mummies of small animals (cats and falcons) to show moving images of them, acquired using tomographic techniques.

The precise manipulation of three-dimensional images can inspire students towards the development of new 3D image processing systems. At a Swedish hospital, Egyptian mummies were scanned using a standard medical CT system. The processing of the data, done in an excellent manner, manages to show the various case layers, thus providing a three-dimensional representation of great interest (see <https://www.youtube.com/watch?v=WSJ1hWISITE>).

In conclusion, with the development of instrumentation, methods of numerical image analysis, improvements in X-ray sources and detectors, and advances in computing techniques for 3D imaging, three-dimensional CT is proving to be a very effective technique for the study of objects of archaeological interest, and also for their restoration and conservation. Recently, with new multi-core computers, the processing of three-dimensional images has become faster, thus arousing great interest, especially among young people, who are accustomed to using apps and tablets. In conclusion, even in archaeology—as in many other fields of scientific interest—excellent results can be obtained only through cooperation between archaeologists, restorers, physicists, and experts in digital image processing.

Archaeology and Tourism

CRISTINA OEHMICHEN-BAZÁN

Universidad Nacional Autónoma de México, Mexico

Archaeology has had a contradictory relationship with tourism. On the one hand, the need to disseminate findings and obtain resources has opened up archaeology to the great world of visitors, fans, and tourists eager to increase their cultural capital. On the other hand, there is a well-founded fear of the trivialization and commercialization of vestiges and archaeological zones, due to the arrival of tourists

Archaeological tourism is part of cultural tourism (Herbert 1995). Tresserras (2004, 2) defines archaeological tourism, or archaeo-tourism, as that type of tourism in which archaeological resources become attractions for tourists and/or when the main motivation of the trip is the visit to the archaeological zones, often encouraged by the diffusion of magazines like *National Geographic* and other publications.

Growth of archaeological tourism

Tourism has been a growing industry, especially since the 1980s. According to the *UNWTO World Tourism Barometer*, in 2016, around 1.2 billion international tourists traveled around the world. This makes tourism an important source of foreign currency and an activity that generates jobs whose income impacts the Gross Domestic Product of many countries. As part of this increase, archaeological tourism has also grown. The increase of visitors to archaeological sites in recent decades has been favored also by the declarations on the cultural heritage of humanity on the part of UNESCO (Moreno and Sariego López 2017).

To mention just a few examples, in 2016, 13 million tourists arrived in Cancun, Mexico, of which 2.1 million visited the archaeological zone of Chichén Itzá; 1.7 million visited Tulum;

and Palenque received 655,417 visits. The case of Peru is also eloquent. The number of tourists visiting Machu Picchu grew strongly in the past quarter century, from only 77,295 visitors in 1991 to 1,282,515 tourists in 2015 (Alonso Schwarz 2012). In 2016, almost 1.3 million tourists arrived at this international archaeological zone.

Another illustrative example is that of Angkor, Cambodia. Since the declaration of the archaeological site of Angkor as a World Heritage Site in 1992, shortly after the Paris Peace Accords ended two decades of warfare, tourism development has allowed Cambodia to strengthen its economy. That country received in 1993 a little more than 100,000 tourists; in 2008 it received more than 2 million (Moreno Melgarejo 2013, 112). A similar case is that of Guatemala, whose tourism has become one of the main sources of income after the civil war ended in 1996, where its archaeological sites are one of the main tourist attractions, along with its enormous ethnic and cultural diversity (Sánchez-Espinosa 2017).

In mature tourist destinations, such as the United Kingdom, Spain, and Greece, the number and scale of visits to archaeological sites by tourists has been increasing. For example, in Spain, research projects and the enhancement of archaeological heritage have allowed access to a large part of the country's archaeological resources, with a projection towards the international market. Investments have been made in new museum equipment, the renovation of museums, and the musealization of large archaeological sites.

Archaeological tourism has influenced the creation of products of all kinds to bring archaeology to visitors. The thematic routes stand out, such as Íberos Route 16, the Celtiberia Route, and the Roman Bética Route. There are also shows and celebrations of historical recreation. Tourists are invited to take gastronomic tours of ancient times, or to stay in hotels that preserve Roman archaeological remains in their interior (Tresserras 2004, 3). In the same way, in Mexico, light-shows in the archaeological sites of

Teotihuacan and Chichén Itzá have allowed the international promotion of tourism (Villalobos-Acosta 2013).

Archaeology in tourism is so important that it is already a market segment. Tresserras (2004, 2) points out that archaeological tourism or archaeo-tourism consists of activities in which archaeological resources become attractions for tourists and/or when the main motivation of the trip is the visit to the archaeological zones.

Relationship of archaeology and tourism

Archaeology and tourism have had a contradictory relationship. While the visit of tourists to archaeological sites and museums has increased throughout the world, the archaeological community does not have a coordinated position regarding this phenomenon. Pinter (2005, 11) points out that there is no consensus on the role tourism has with archaeology. For some archaeologists, tourist activity is a way to attract resources for research and site protection. For others, tourist activity is eminently destructive, as the interests of the market compete with scientific interests. For their part, some sectors in the tourism industry consider archaeologists and their institutions as an obstacle to the development of tourist destinations (Walker and Carr 2013, 20).

Despite the importance of archaeology to tourism, it is difficult to find tourists who travel only for archaeological reasons. Visits to archaeological sites and museums are usually integrated into the trip as an important component in many tourist destinations, but they are not the only reason for traveling. Other frequent components in tourist trips include gastronomy, landscape, the attractions of contemporary culture, and a more generalized historical interest.

The relationship between tourism and archaeology becomes even more complex due to the emergence of a new subject: the indigenous movements. Since the 1970s, native peoples have claimed their right to the human remains located in their territories, as well as to the archaeological sites and material objects built or manufactured by their ancestors. In the United States, Canada,

New Zealand, and Australia, indigenous movements have promoted changes in the legislation on human remains located in the ancestral lands (Díaz-Andreu 2014). They have also had an impact on the content and organization of museums. It is estimated that in the United States, the 1990 Native American Graves Protection and Repatriation Act has caused one-and-a-half million objects to return to native communities. In Latin America, indigenous organizations such as the Maya in Mexico and Guatemala, and the Mapuches in Chile and Argentina claim their participation in the administration and management of archaeological sites and museums.

Assessment: Heritage Impact (HIA)

AYESHA PAMELA ROGERS

National College of Arts, Lahore, Pakistan

Origins of Heritage Impact Assessment

Impact assessment evolved during the 1960s in response to growing public interest in the protection of the environment from the consequences of development, using models and approaches from the natural sciences, particularly ecology. The aim was to empower the environment in decision-making and development planning. The success of the impact assessment model as a planning tool since the beginning of the sustainable development debate of the 1970s led to its wider application, including applications to heritage. It was first applied to archaeological resources of known importance that were threatened with destruction due to infrastructure development projects. Impact assessment applied to archaeological and other heritage resources is now gaining universal acceptance as an essential development planning and heritage management tool.

Heritage Impact Assessment (HIA) fits into a comprehensive assessment process that links several levels of engagement: Strategic Impact Assessment (SIA) which deals with the potential impacts that will result from area-wide plans or major policy decisions; Environmental Impact Assessment (EIA) which deals with the ascertained impacts that will result from a specific development project, and HIA which is applied to specific project and development proposals that potentially threaten resources of cultural significance.

HIA is a systematic process of identifying the probable results of a proposed policy or action on the heritage of a place and its communities. It is a decision support tool which provides input at the planning, works and operational stages to minimize or eliminate adverse effects through mitigation and to enhance positive impacts. In

places where heritage is included in the EIA system as a component on a legal par with other environmental variables, practice has clearly shown the power of rigorous HIA as a tool to manage change and mitigate risk in order to preserve significance—the basic task of heritage management. As such, it is rapidly becoming the heritage manager's most important tool for managing change in historic resources.

Why is HIA needed?

The aims of HIA are to identify heritage resources, assess potential impacts and mitigate them with a view to preserving and safeguarding heritage resources. HIA is not a proposal for optional scenarios or a statement of heritage's self-evident importance. What it must be is a measured, thorough presentation of facts and arguments and a realistic set of proposals for remedial and ameliorative action. It is the professional task of the HIA practitioner to find an acceptable approach which will preserve heritage values, satisfy as many stakeholders as possible, and be financially viable and practicable in conservation terms.

The assessment of impacts on heritage is needed today as cultural resources are being not only lost to development, but also exploited at an unsustainable rate. Heritage managers are faced with two principal challenges: ensuring the continuity and continued relevance of culture in the community and protecting both the fabric and significance of heritage assets from exploitation, misuse and degradation as a result of change.

HIA provides the methodology to safeguard the integrity of heritage resources in the face of these threats from development, or other scenarios of external change; to negotiate a sustainable balance between the forces of change, progress, and conservation in ways that maintain the authenticity of the threatened heritage, preserving its significance, meaning, and function in the life of the community; and to mitigate the adverse impacts of development and change, enhancing and adding value to the heritage as a result.

What type of heritage is assessed?

There are different definitions of what type of heritage should be assessed in an HIA. Tangible, immovable heritage is accepted as the main focus with an emphasis on listed, nationally, and internationally protected heritage. Intangible heritage, however, is not considered in the HIA processes of international funding agencies and many national frameworks. When referred to it is often restricted to discussion of ways that intangible resources can be “used” for commercial purposes or in the restricted context of safeguarding the cultural heritage of indigenous peoples (IFC 2012).

The setting of heritage resources is another critical component of their significance and authenticity which is often neglected by the HIA process, despite such recommendations as the Xi'an Declaration (ICOMOS 2005) article 8.

Some systems recommend that given constraints of time and money, assessment should focus on the most significant impacts in order of priority; the problem with this approach is one of sequence where someone has to identify what are the “most significant impacts” before the impact assessment itself is carried out (Campbell 2009). This concept of “critical cultural heritage” is dangerous as it implies that only high-profile, legally protected and well-defined “used” resources need focused protection.

One of the thorniest issues in HIA is that of “potential” heritage. Resources which have legal protection or international recognition are guaranteed to receive attention, with other resources positioned along a diminishing scale of likelihood. At the bottom lie the vast undocumented areas of archaeological and heritage potential. Most frameworks provide no guidance on how to tackle predictive modeling, sampling, or investigative survey and instead rely at best on “chance finds” procedures, emergency excavation, or relocation, and at worst lead to loss of valuable places. This is a matter of particular urgency for countries with large tracts of unstudied and undocumented potential.

HIA methodology
